Cardiovascular Monitoring

BECKY SCHROEDER, JONATHAN MARK, and ATILIO BARBEITO

KEY POINTS

- Monitoring of the electrocardiogram (ECG) provides continuous monitoring of heart rate, identification of arrhythmias and conduction abnormalities, and detection of myocardial ischemia.
- Accurate and reliable ECG monitoring requires attention to lead placement and selection, choice of filter, and gain that will influence the displayed ECG tracing.
- An anterolateral precordial lead (V_3, V_4, or V_5) should be selected for the most sensitive detection of myocardial ischemia.
- Demand-mediated subendocardial ischemia resulting in ST-segment depression is the most commonly observed form of perioperative ischemia. ST-segment depression is most commonly observed in an anterolateral precordial lead regardless of the coronary territory responsible.
- Supply-mediated transmural ischemia resulting in ST-segment elevation is uncommonly observed intraoperatively except during cardiac operations. In contrast to ST-segment depression, ST-segment elevation is indicative of the myocardial territory and coronary artery involved.
- Most automated noninvasive arterial blood pressure measuring devices use an oscillometric measurement technique and rarely cause complications. Caution should be exercised in patients who cannot complain of arm pain, those with irregular rhythms that force repeated cuff inflation, and those receiving anticoagulant therapy.
- The Allen test for palmar arch collateral arterial flow is not a reliable method to predict complications from radial artery cannulation. Despite the absence of anatomic collateral flow at the elbow, brachial artery catheterization for perioperative blood pressure monitoring is a safe alternative to radial or femoral arterial catheterization.
- The accuracy of a directly recorded arterial pressure waveform is determined by the natural frequency and damping coefficient of the pressure monitoring system. Optimal dynamic response of the system will be achieved when the natural frequency is high, thereby allowing accurate pressure recording across a wide range of damping coefficients.
- The preferred position for alignment (or “leveling”) of external pressure transducers for measuring arterial or central venous pressure (CVP), which eliminates confounding hydrostatic pressure artifacts, lies approximately 5 cm posterior to the sternomanubrial junction. The more conventional location for the reference level used for hemodynamic monitoring including central venous and pulmonary artery pressures, is the mid-thoracic level, which corresponds most closely to the mid-left atrial position and is located halfway between the anterior sternum and the bed surface in the supine patient.
- Because of wave reflection and other physical phenomena, the arterial blood pressure recorded from peripheral sites has a wider pulse pressure than when measured more centrally.
- Dynamic measures of cardiac preload, such as stroke volume and pulse pressure variation, are better predictors of intravascular volume responsiveness than static indicators, such as CVP and pulmonary capillary wedge pressure.
- Selecting the best site, catheter, and method for safe and effective central venous cannulation requires that the physician consider the purpose of catheterization, the patient’s underlying medical condition, the intended operation, and the skill and experience of the physician performing the procedure. Right internal jugular vein cannulation is preferred due to its consistent, predictable anatomic location and its relative ease of access intraoperatively.
- Mechanical complications from central venous catheters can be decreased by the use of ultrasound vessel localization, venous pressure measurement before large catheter insertion, and radiographic confirmation that the catheter tip lies outside the pericardium and parallel to the walls of the superior vena cava.
- CVP is the result of a complex and diverse interplay among many different physiologic variables, the main ones being venous return and cardiac function. No simple relationship exists between CVP and circulating blood volume. Despite this, important pathophysiologic information can be obtained by careful assessment of the CVP waveform morphology.
- Catheter misuse and data misinterpretation are among the most common complications of central venous and pulmonary artery catheters.
- Pulmonary artery wedge pressure is a delayed and damped reflection of left atrial pressure. The wedge pressure provides a close estimate for pulmonary capillary pressure in many cases, but it may underestimate capillary pressure when postcapillary pulmonary vascular resistance is increased, as in patients with sepsis.

- Use of central venous, pulmonary artery diastolic, or pulmonary artery wedge pressures as estimates of left ventricular preload is subject to many confounding factors, including changes in diastolic ventricular compliance and juxtacardiac pressure.
- Pulmonary artery catheter monitoring has not been shown to improve patient outcomes. Reasons cited for these results include misinterpretation of catheter-derived data and failure of hemodynamic therapies that are guided by specific hemodynamic indices.
- Thermodilution cardiac output monitoring, the most widely used clinical technique, is subject to measurement errors introduced by rapid intravenous fluid administration, intracardiac shunts, and tricuspid valve regurgitation.
- Mixed venous hemoglobin oxygen saturation is a measure of the adequacy of cardiac output relative to body oxygen requirements. This measurement is also dependent on the arterial hemoglobin oxygen saturation and hemoglobin concentration.

Introduction to Cardiovascular Monitoring: Focused Physical Examination

Electronic devices currently provide the vast majority of information used in monitoring a patient's cardiovascular status. However, the physician's senses, augmented by clinical context, continue to provide global insight into the patient's condition and remain critical in evaluating, and interpreting data derived from other sources.[1] Manual palpation of an arterial pulse will differentiate true asystole from monitoring artifact more efficiently than troubleshooting any monitor. Regardless of the manner used, though, it is important to understand the strengths and limitations of monitoring techniques.

Heart Rate and Pulse Rate Monitoring

The ability to estimate the heart rate quickly with a "finger on the pulse" is as important as this expression is common despite near-universal use of electronic devices for continuous monitoring. The electrocardiogram (ECG) is the most common heart rate monitoring method used in the operating room, even though any device measuring the period of the cardiac cycle will suffice. Accurate detection of the R wave and measurement of the interval from the peak of one QRS complex to the peak of the next on an ECG (R-R interval) serve as the basis from which digitally displayed values are derived and periodically updated (e.g., at 5- to 15-second intervals) (Fig. 36.1).[2]

The distinction between heart rate and pulse rate lies in the difference between electrical depolarization with systolic contraction of the heart (heart rate) and a detectable peripheral arterial pulsation (pulse rate). Pulse deficit describes the extent to which the pulse rate is less than the heart rate and may arise in conditions such as atrial fibrillation in which stroke volume is periodically compromised by a very short R-R interval to such an extent that no arterial pulse is detectable for that systolic ejection. Electrical-mechanical dissociation and pulseless electrical activity are extreme examples of pulse deficit in which cardiac contraction is completely unable to generate a palpable peripheral pulse. The heart rate is reported from the ECG trace and the pulse rate from the pulse oximeter plethysmograph or arterial blood pressure monitor. Considering both in monitoring and clinical evaluation improves accuracy and reduces measurement errors and false alarms.[3]

Electrocardiography Monitoring

The value and importance of intraoperative monitoring of the ECG is evidenced by its requirement as a basic circulatory monitoring standard by the American Society of Anesthesiologists (ASA)[4]: "Every patient receiving anesthesia shall have the ECG continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location." Similar recommendations have been recently updated by the American Heart Association (AHA) to guide indications, duration, and implementation of ECG monitoring in hospitalized patients outside of the operating room.[5]

The three primary reasons for ECG monitoring are continuous monitoring of heart rate, identification of arrhythmias and conduction abnormalities, and detection of myocardial ischemia. Furthermore, with many patients coming to surgery with pacemakers or implantable cardiac defibrillators in place, the ECG monitor enables the anesthesiologist to follow the proper function of these devices during the perioperative period. (Perioperative management of these devices is described in Chapter 38.) In order for bedside ECG monitoring to be accurate and effective, the clinician must attend to proper lead placement and selection, filter mode, and gain adjustment.

ELECTROCARDIOGRAM LEAD PLACEMENT AND SELECTION

Standard Lead Systems

Current operating room and intensive care monitoring systems have five leads that allow monitoring of the standard limb leads (I, II, III), the augmented limb leads (aVR, aVL, aVF), and a single precordial lead (V_1, V_2, V_3, V_4, V_5, or V_6). Typically, two of these 12 standard leads are simultaneously displayed on the bedside monitor. Historically, the augmented limb leads and precordial leads were described as *unipolar*, whereas the standard limb leads were described as *bipolar*. A recent scientific statement from the AHA and others[6] discourages this distinction because in effect, all the lead configurations are effectively bipolar in their recording of surface electrical potentials.

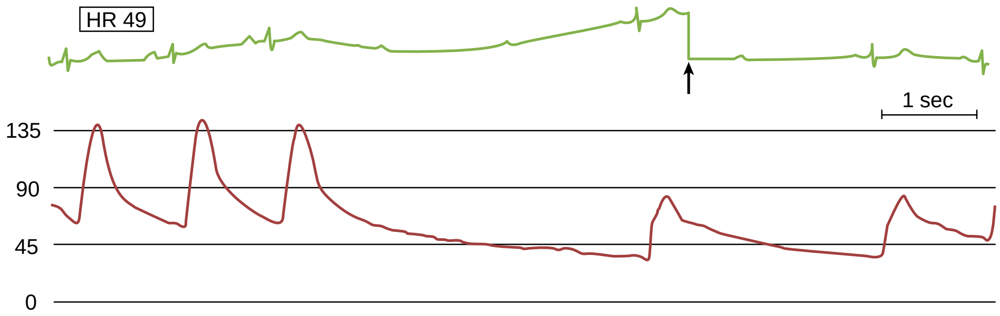

Fig. 36.1 Digital heart rate *(HR)* displays may fail to warn of dangerous bradyarrhythmias. Direct observation of the electrocardiogram (ECG) and the arterial blood pressure traces reveals complete heart block and a 4-second period of asystole, whereas the digital display reports an HR of 49 beats/min. Note that the ECG filter *(arrow)* corrects the baseline drift so that the trace remains on the recording screen. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

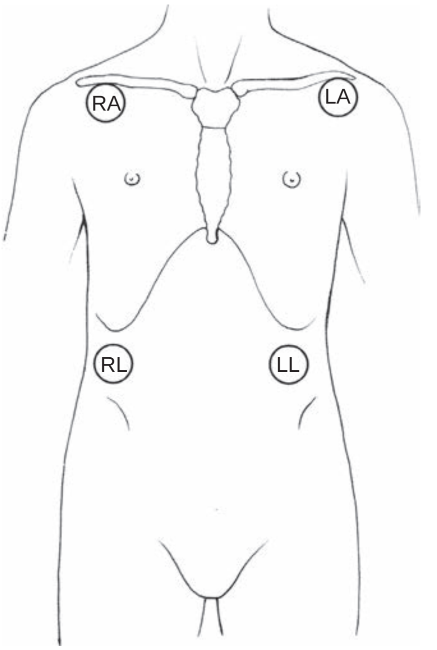

Fig. 36.2 Standard ECG limb lead placement for patient monitoring. *LA*, Left arm; *LL*, left leg; *RA*, right arm; *RL*, right leg. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone;1998.)

Based on AHA guidelines, ECG monitoring leads have a standard color-coding system: right arm (white), left arm (black), right leg (green), left leg (red), and precordial lead (brown). Of note, this color scheme is not the same used internationally or the one recommended by the International Electrotechnical Commission. Unlike recording a standard 12-lead ECG, where the limb leads are attached to electrodes placed on the wrists and ankles or arms and legs, when monitoring patients in the operating room or intensive care unit (ICU), the limb leads are typically placed on the torso, with the right and left arm leads placed just below the clavicles and the leg leads placed above the hips (Fig. 36.2). Of note, placement of the right leg lead (green lead) can be anywhere on the body because it is a ground electrode, and its location will not alter the display of any of the selected standard leads.[7]

Placement of the limb electrodes on the torso has been utilized since 1966, when Mason and Likar introduced a variation on positioning the standard limb electrodes of the 12-lead ECG during exercise stress testing to minimize artifacts in the limb leads caused by movement.[8] Although the limb lead QRS complexes are slightly different in amplitude and axis, and the precordial leads may vary slightly from the standard 12-lead ECG recording, studies have shown that the ST-segment measurements during exercise stress testing were generally similar when the Mason-Likar 12-lead ECG system is used, as compared with the standard 12-lead ECG.[8-11] Consequently, torso-positioned limb leads have become standard for monitoring in the operating room and ICU because of convenience and the potential to obviate motion artifact.

In some cases, surgical incisions, patient positioning, or other procedural aspects may mandate adjusting these limb lead electrode locations. However, for reliable recording of standard limb leads, the electrodes must be outside the cardiac borders, in the transverse plane above and below the heart, and in the sagittal plane to the left and right of the heart (Fig. 36.3). In practice, limb lead placement closer to the heart may lead to unintended distortion of the ECG tracings.[10]

Placement of the precordial lead (brown) electrode requires more attention than the limb leads, since this lead is often misplaced and its position is critical for the reliable and sensitive detection of myocardial ischemia. The V_5 precordial lead is the one most commonly chosen for monitoring patients at risk for myocardial ischemia, since historically it has been shown to be the most sensitive single lead for detecting ischemia during exercise stress testing[12,13] and during anesthesia.[14,15] Importantly, the V_5 precordial lead can be monitored during cardiac operations without interfering with the surgical prep and median sternotomy incision. For patients undergoing other operations, particularly high-risk patients undergoing vascular procedures, leads V_4 or V_3 may be chosen because there is good evidence that these leads are even more sensitive for detecting prolonged postoperative myocardial ischemia.[16]

Standard locations for the six precordial lead electrodes are shown in Fig. 36.4. Given that there is considerable evidence that precordial lead placement is inaccurate even during diagnostic 12-lead ECG recordings,[6] it is likely that this is also commonplace during ECG monitoring in the operating room and ICU. Accurate lead placement is facilitated by locating the manubrial-sternal junction, its immediately inferior rib interspace (the second), and then palpating down to identify the fourth and fifth interspaces for accurate precordial lead location. Note that lead V_4 lies

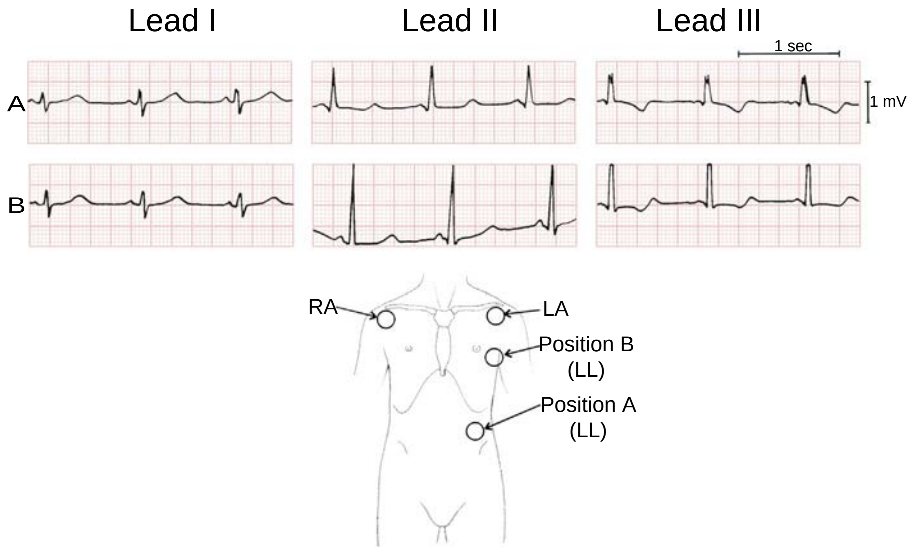

Fig. 36.3 Importance of ECG limb lead placement. ECG recording of leads I, II, and III from position A, with the left leg *(LL)* lead in the standard location below the heart near the left iliac crest compared with position B, with the LL lead placed over the precordium (near the V_5 position). Standard ECG limb lead positioning should be outside the cardiac borders, as shown here in position A. If the LL lead electrode is placed inappropriately in position B, the recording of leads II and III will be modified. Note, however, that the recording of lead I is not affected by the misplaced LL lead, since lead I measures the difference between left arm *(LA)* and right arm *(RA)* electrodes. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

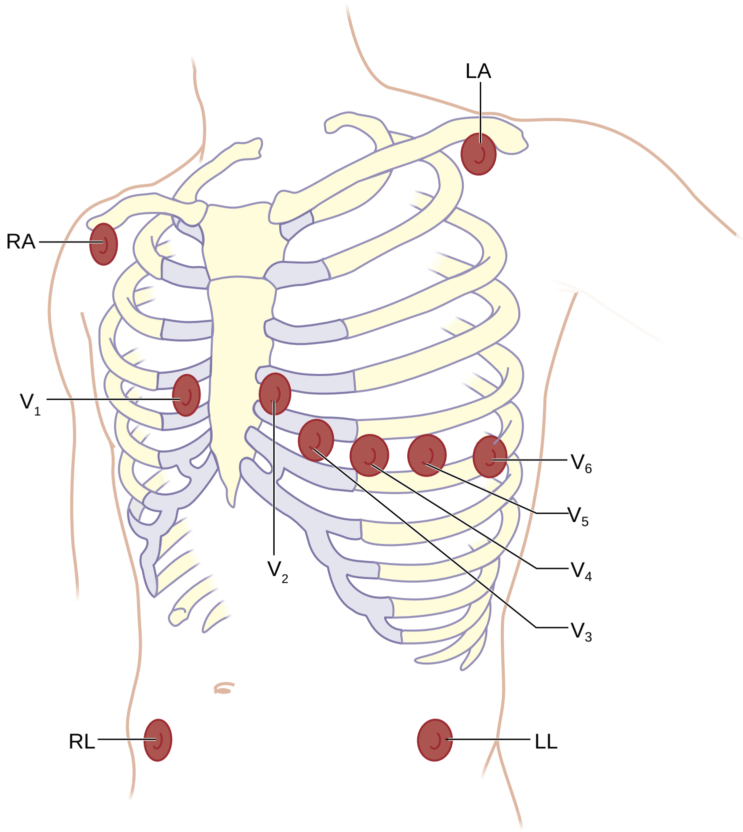

Fig. 36.4 Proper anatomic location of the six standard precordial ECG leads. Precise positioning of the lateral precordial leads is ensured by identifying the fifth intercostal space in the mid-clavicular line for lead V_4, moving laterally to the anterior axillary line for V_5, and further laterally to the mid-axillary line for V_6. *LA*, Left arm; *LL*, left leg; *RA*, right arm; *RL*, right leg.

in the fifth interspace at the mid-clavicular line, and leads V_5 and V_6 are located directly lateral to V_4 in the anterior and mid-axillary lines, respectively.

Given anatomic considerations and the strong evidence that the mid-precordial leads (V_3, V_4, V_5) are best for detection of ischemia, it is important that the precordial lead not be placed haphazardly or too laterally. In some cases (e.g., patients undergoing left thoracotomy), none of these precordial lead placement sites are possible. In this instance, it is reasonable to choose another standard lead position, such as V$_1$, but it is important that the clinician recognize that ECG monitoring for ischemia will not be as sensitive.

Alternative Lead Systems

Electrocardiographic evidence for right ventricular (RV) ischemia and infarction is best identified by right-sided precordial leads, particularly lead V$_{4R}$, a mirror image of the V$_4$ lead, positioned in the fourth intercostal space at the midclavicular line. Although never chosen for routine ischemia monitoring, this lead has proven valuable for detecting RV ischemia and infarction, and might be chosen to monitor patients at risk for inferior left ventricular (LV) ischemia, which is commonly accompanied by RV involvement.[6,17]

Three-lead ECG monitoring systems, while less common today than five-lead systems, remain available particularly in non-operating room procedural settings and for patient transport. A three-lead system is also the standard ECG monitoring system incorporated in external defibrillator devices. The three leads (right arm, left arm, left leg) can be placed in similar locations to their five-lead system counterparts, and this allows reliable monitoring of heart rate, detection of R waves for synchronized direct current cardioversion, and monitoring for potentially life-threatening arrhythmias such as ventricular fibrillation. These systems are more limited than five-lead systems (or standard 12-lead ECG recordings) for diagnosing more complex arrhythmias and detection of myocardial ischemia. Modifications of these standard limb leads allow better sensitivity for ischemia monitoring by placing the positive (left arm) electrode in the standard precordial V$_5$ position and selecting an appropriate limb lead (usually lead I) to create this modified lead recording. These three-lead variations useful for ischemia monitoring are created by placing the right arm lead in the following locations: CS$_5$ (central subclavicular), CM$_5$ (central manubrial), CB$_5$ (central back), and CC$_5$ (central chest) (Fig. 36.5). Each of these lead recordings will be a modification of the standard precordial V$_5$ lead, and owing to differences in R-wave amplitude and ST-segment morphology, may lead to over- or underestimation of ST-segment changes.[18]

Another modified three-lead system is a surrogate for precordial lead V$_1$. This lead (MCL$_1$) is recorded by placing the left arm lead in standard position, the left leg lead at the V$_1$ position, and selecting lead III (see Fig. 36.5). This modified lead system is useful for monitoring in the ICU or other circumstances where detection of P-wave morphology and arrhythmias is of paramount importance.

Following cardiac surgical procedures, recording the ECG signal from an epicardial atrial pacing wire may also be useful for detecting P waves that may not be as evident from skin surface ECG recordings (Fig. 36.6). This alternative lead recording is usually performed in the ICU using a 12-lead ECG system and attaching one of the atrial pacing wires to a precordial lead wire.

ELECTROCARDIOGRAM FILTER SELECTION

The ECG signal is subject to artifacts (noise) both in the low-frequency and high-frequency ranges. Consequently, all ECG monitors use bandpass filters to narrow the signal bandwidth, preserving the signal of interest while reducing artifacts and improving signal quality. As the name suggests, a bandpass filter allows signal frequencies within a certain range to pass or be displayed, while attenuating or functionally eliminating signal frequencies both at a low range and a high range.

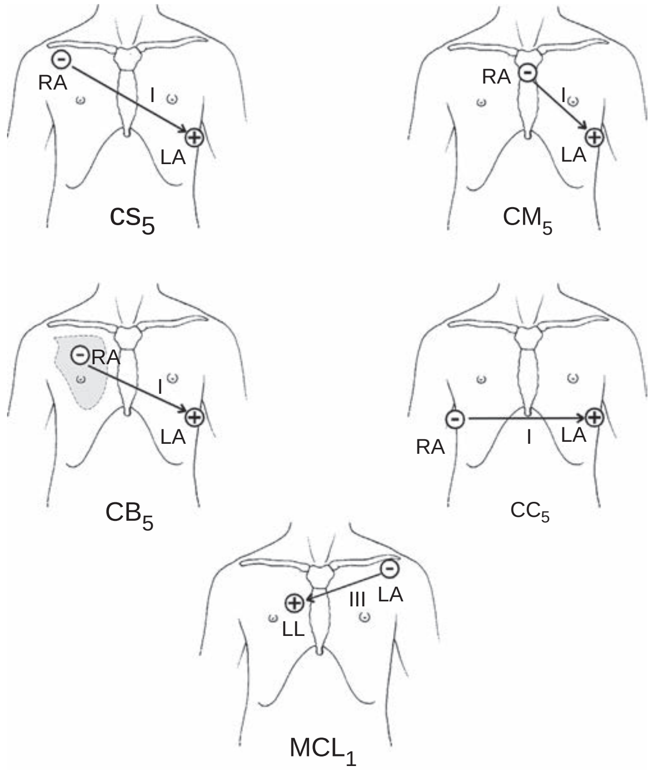

Fig. 36.5 When only a three-electrode lead set is available, modified bipolar limb leads may be recorded as surrogates for standard precordial leads. Alternatives to precordial lead V$_5$ are recorded by selecting lead I on the bedside monitor and placing the positive exploring left arm *(LA)* electrode in the V$_5$ position. The nomenclature describing these leads derives from the location of the positive exploring electrode located in the V$_5$ position and the negative right arm *(RA)* electrode position being located as follows: *(CS$_5$)* central subclavicular, *(CM$_5$)* central manubrial, *(CB$_5$)* central back (shown overlying the right scapula), and *(CC$_5$)* central chest. In contrast, note that the *(MCL$_1$)* lead (modified central lead 1) is recorded by selecting lead III on the bedside monitor and placing the positive exploring left leg *(LL)* electrode in the V$_1$ position with the negative LA lead in a modified position beneath the left clavicle. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

Low-frequency artifact is typically caused by respiration or patient movement that causes the ECG tracing to wander above and below the baseline (Fig. 36.7). Often this will appear as the ECG tracing being cut off or only partially displayed on the bedside monitor channel. Therefore, low-frequency filters (also called high-pass filters) are used in ECG monitoring. The heart rate forms a rough lower bound for the frequency content of the ECG signal and is measured in Hertz (Hz, cycles per second). Since heart rates slower than 40 beats per minute (bpm) (0.67 Hz) are uncommon, traditional low-frequency analog filters are used to cut off signals at frequencies below 0.5 Hz. However, such filters may introduce considerable distortion into the ECG, particularly with respect to the level of the ST segment, resulting from phase nonlinearities that occur in areas of the ECG signal where frequency content and wave amplitude abruptly change, as occurs where the end of the QRS complex meets the ST segment. The 1975 AHA recommendations included

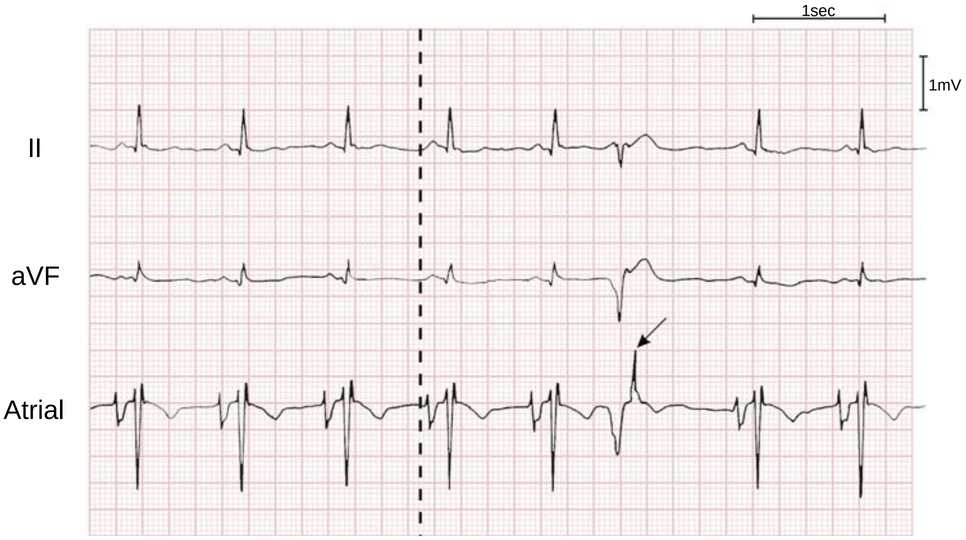

Fig. 36.6 Simultaneous recording of surface ECG leads II and aVF and an atrial epicardial lead *(atrial)* recorded from a pacing wire attached to the surface of the right atrium. Onset of atrial electrical activity is denoted by the P wave in the surface leads and marked by the dashed vertical line. Note that the amplitude of the atrial electrical signal is greatest in the atrial lead recording. In addition, the sixth beat is a ventricular premature beat, and the resulting retrograde atrial depolarization is clearly evident in the atrial lead *(arrow)* but not seen as easily in standard surface ECG leads II or aVF. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

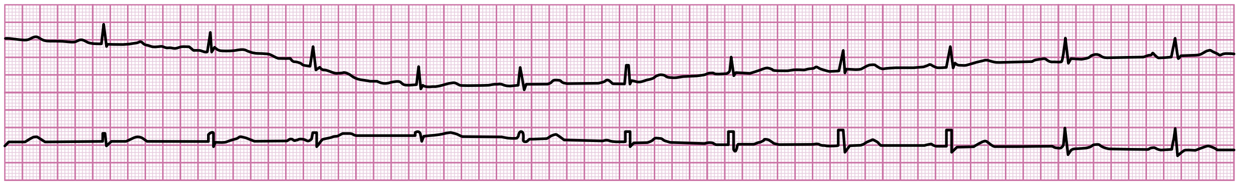

Fig. 36.7 ECG recording of lead II *(top)* and lead V_5 *(bottom)* at standard speed (25 mm/s) and gain (10 mm/mV) with a diagnostic bandpass filter. The respiratory artifact is evident from the varying or wandering baseline most noticeable in lead II. This artifact will be eliminated by using the monitor bandpass filter.

a 0.05-Hz low-frequency cutoff for diagnostic ECGs. This recommendation preserves the fidelity of repolarization, but baseline drift can still be a problem. Current modern digital filtering provides more sophisticated methods for a higher cutoff for low-frequency filtration without those phase distortions observed with analog filtering. Thus, to reduce artifactual distortion of the ST segment, current AHA recommendations suggest the low-frequency cutoff should be either 0.05 Hz for monitors with analog filters or 0.67 Hz or below for monitors and ECG recording devices with linear digital filters with zero phase distortion.[6]

High-frequency ECG artifacts are typically caused by muscle fasciculations, tremors, and most importantly, the ever present 60 cycle (Hz) electromagnetic interference from other electrical equipment in the monitoring environment. These artifacts can be eliminated with high-frequency filters (also termed low-pass filters), but like low-frequency filters, the high-frequency filters may distort the ECG signal in undesirable ways. The higher frequencies in the ECG signal include features such as rapid upstroke velocity (QRS complex), peak amplitude (R wave), and waves of short duration. Most importantly, pacing spikes, which by definition are high frequency and low amplitude, are often eliminated by high-frequency filters and make bedside identification of pacemaker function impossible. A high-frequency cutoff of 100 Hz was considered adequate by the AHA in 1975 to maintain diagnostic accuracy during visual inspection of an ECG, although it has long been recognized that higher-frequency components of the QRS complex may have clinical significance in patients with various forms of heart disease. According to current AHA recommendations, to measure routine duration and amplitudes accurately in adults, adolescents, and children, an upper frequency cutoff of at least 150 Hz is required, and an upper frequency cutoff of 250 Hz is more appropriate for infants.[6]

Current ECG monitors allow the clinician a choice among several filtering modes or bandwidths. The actual filter frequencies tend to vary among manufacturers, but in general there are three different filters that may be selected, termed diagnostic mode, monitoring mode, and filter mode. The ***diagnostic mode*** typically has a bandpass of 0.05 to 150 Hz, and this filter should always be selected for the most undistorted and accurate display of the ST segment and the identification of pacing spikes. The ***monitor mode*** typically has a bandpass of 0.5 to 40 Hz, and while both low-frequency (respiratory drift) and high-frequency (60 Hz) noise is reduced or attenuated, the ST segments are often distorted and typically show an exaggerated deviation that is artifactually introduced by the filter (Figs. 36.8A and B).[19] The ***filter mode*** bandpass is 0.5 to 20 Hz and may incorporate a notch filter aimed at further attenuating and eliminating 60 Hz interference from nearby electrical equipment.

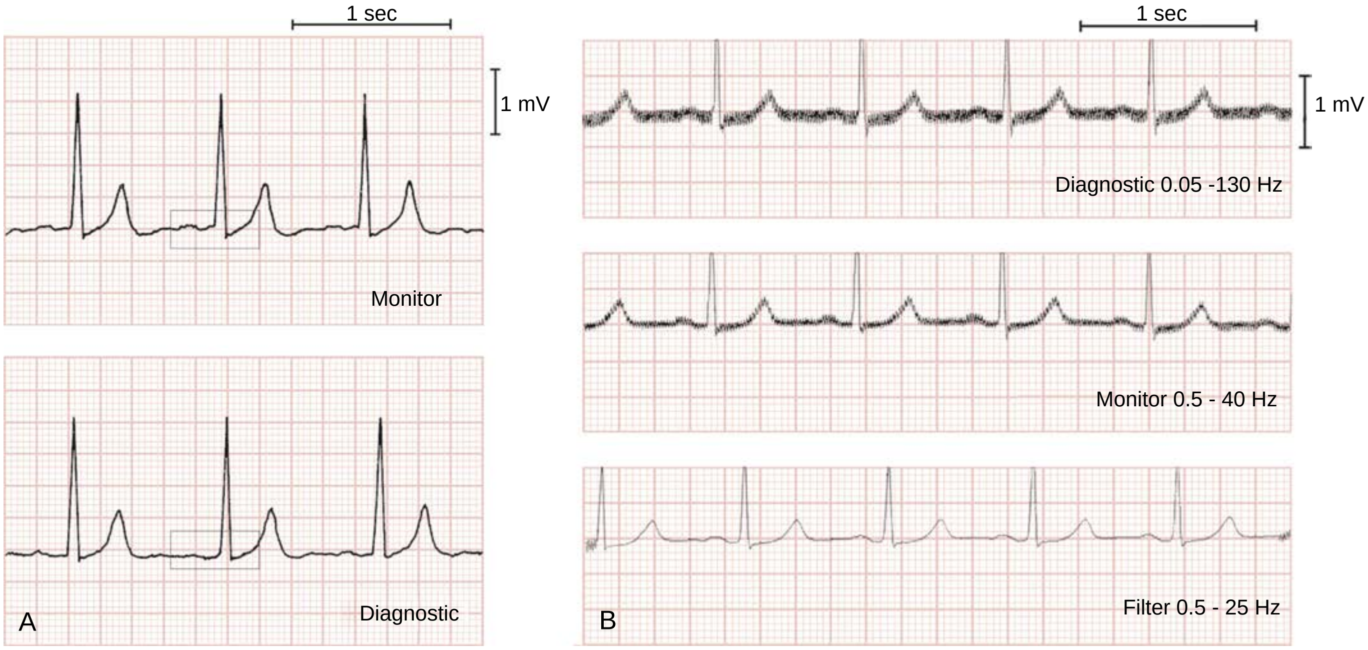

Fig. 36.8 Effects of filter selection on the ST segment. Application of the monitor mode filter (8A, *top panel*) produces artifactual J-point depression and upsloping ST-segment depression *(box)*. These abnormalities are not seen when the diagnostic mode filter (8A, *bottom panel*) is used to record the ECG. Filter selection also effects ECG electrical interference originating from the wall power source (8B). Compared to the diagnostic mode filter (bandpass 0.05-130 Hz), the narrower bandpass of the monitor mode (0.5-40 Hz) reduces this high-frequency artifact, and the filter mode (0.5-25 Hz) that incorporates an additional notch filter at 60 Hz eliminates this electrical artifact entirely. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

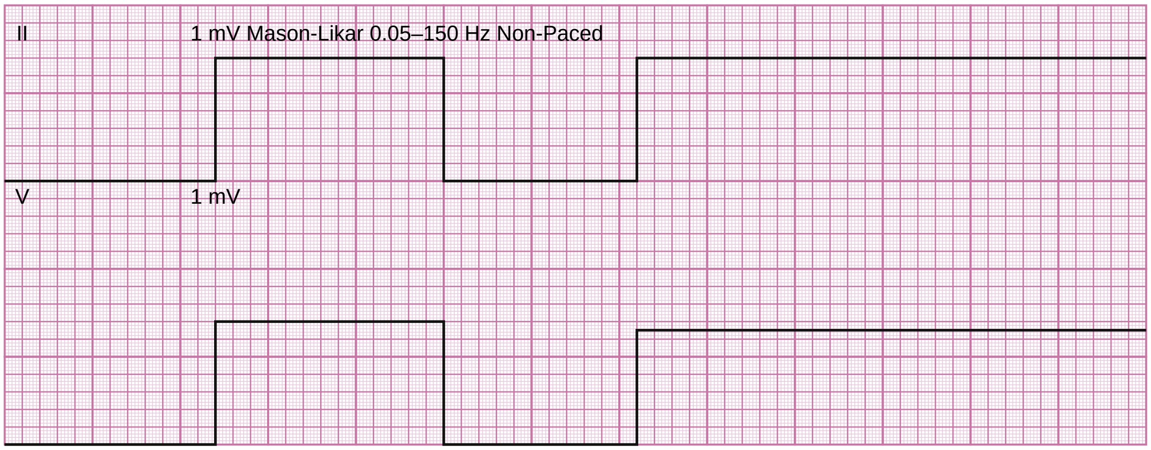

Fig. 36.9 ECG gain is indicated by a 1 mV rectangular calibration signal on a paper recording or by a 1 mV vertical marker at the edge of the bedside monitor ECG waveform. In this example, the ECG is shown at standard gain, 10 mm/mV.

ELECTROCARDIOGRAM GAIN SELECTION

In addition to lead and filter selection, bedside monitors also allow adjustment and selection of the ECG signal gain. A standard ECG is recorded at a gain of 10 mm/mV and is indicated by a 1 mV rectangular calibration signal on a paper recording (Fig. 36.9) or by a 1 mV vertical marker at the edge of the bedside monitor ECG waveform. Bedside monitors may be set to an autogain mode, where the available display space is filled by the ECG tracing and the corresponding increase or decrease from standard gain is indicated by the vertical marker. Alternatively, the clinician may adjust the ECG signal gain manually. This is done when the monitor detection of heart rate is inaccurate. For example, one might reduce the ECG signal gain when the monitor is inappropriately counting a tall T wave as an R wave and displaying an artifactual heart rate that is twice the true rate. Conversely, one would increase the ECG gain when there are very small R waves and the monitor cannot record and display the heart rate.

Gain adjustment is important because all features of the ECG are equally amplified or reduced when the gain is changed from the 10 mm/mV standard. As a consequence, ST-segment deviations can be obscured when gain is reduced and thereby impair clinical observation of important ST-segment changes. Alternatively, if the gain is

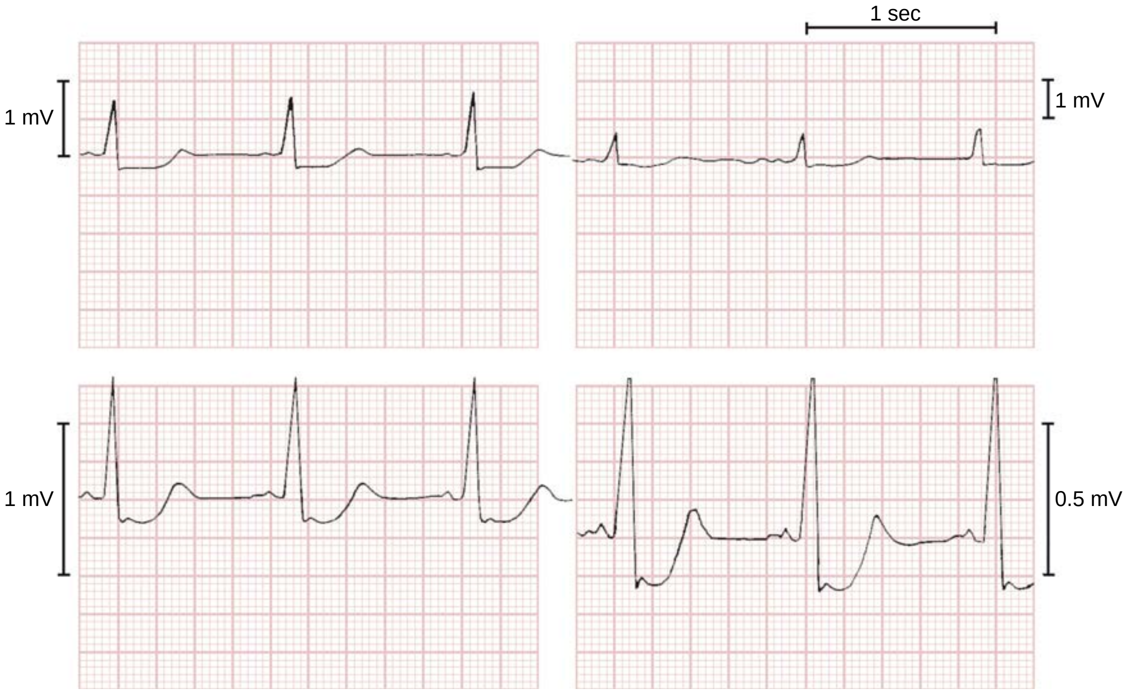

Fig. 36.10 Effect of gain adjustment on the magnitude of ST-segment shift. The magnitude of ST-segment depression and R-wave amplitude vary in direct proportion to overall signal gain denoted by the vertical calibration signals adjacent to the traces (10 mm/mV, *upper left panel*; 5 mm/mV, *upper right panel*; 20 mm/mV, *lower left panel*; 20 mm/0.5 mV or 40 mm/mV, *lower right panel*). Note that at four times standard gain *(lower right panel)*, the ST depression increases to 6 mm but R-wave amplitude only increases to 21 mm because the R-wave peak is "cut off" at the upper limits of the recording display. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

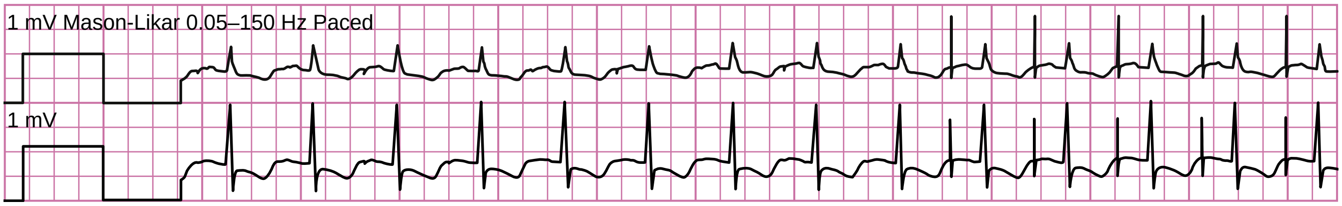

Fig. 36.11 Leads II *(top)* and V_5 *(bottom)* are recorded during atrial pacing (86 beats/min) at standard speed (25 mm/ms) and gain (10 mm/mV). Atrial pacing spikes are small and difficult to discern, particularly in lead V_5. Prior to the 10th beat, the *Pacing Mode* is selected and the monitor marks the atrial pacing spikes clearly on the remaining five beats.

increased, ST deviations will also be amplified proportionally. While common clinical communication of ST-segment shifts is always described in terms of millimeters (mm) of depression or elevation, interpretation of bedside monitor ECG tracings must always be tempered by consideration of the display gain (Fig. 36.10).

ELECTROCARDIOGRAM PACING MODE

While older ECG monitors recorded analog (continuous) signals, current devices convert the analog ECG signal to digital form by sampling the signal at very high rates up to 15,000 times per second.[6] This oversampling of the ECG signal was originally introduced to allow identification and recording of pacemaker stimulus outputs (pacing spikes), which are generally shorter than 0.5 ms, but current systems do not always detect these small-amplitude high-frequency signals reliably. As a result, most bedside ECG monitors now include a ***pacing mode*** selection, which when activated, employs an algorithm to detect and highlight these pacing spikes, making detection of pacemaker function easier. When this monitoring mode is selected, clinicians should recognize that the displayed ECG tracing shows regular markers, often in a different color than the ECG tracing, that indicate and highlight presence of a pacemaker stimulus output. These are not amplified pacemaker signals, but rather monitor-generated markers of their detection. While very helpful to the clinician at the bedside, pacemaker mode monitoring may not reliably detect pacemaker spikes in all patients. In other instances, the intrinsic features of the pacemaker stimulus in different leads might allow their detection in some leads but not others (Fig. 36.11).

ELECTROCARDIOGRAM DISPLAYS AND RECORDINGS

Monitoring the ECG during anesthesia and in the ICU includes both observation of the bedside monitor display and periodic recording of the ECG "rhythm strip" for documentation or more careful analysis. The most common bedside recording system provides a 2-inch strip that records two

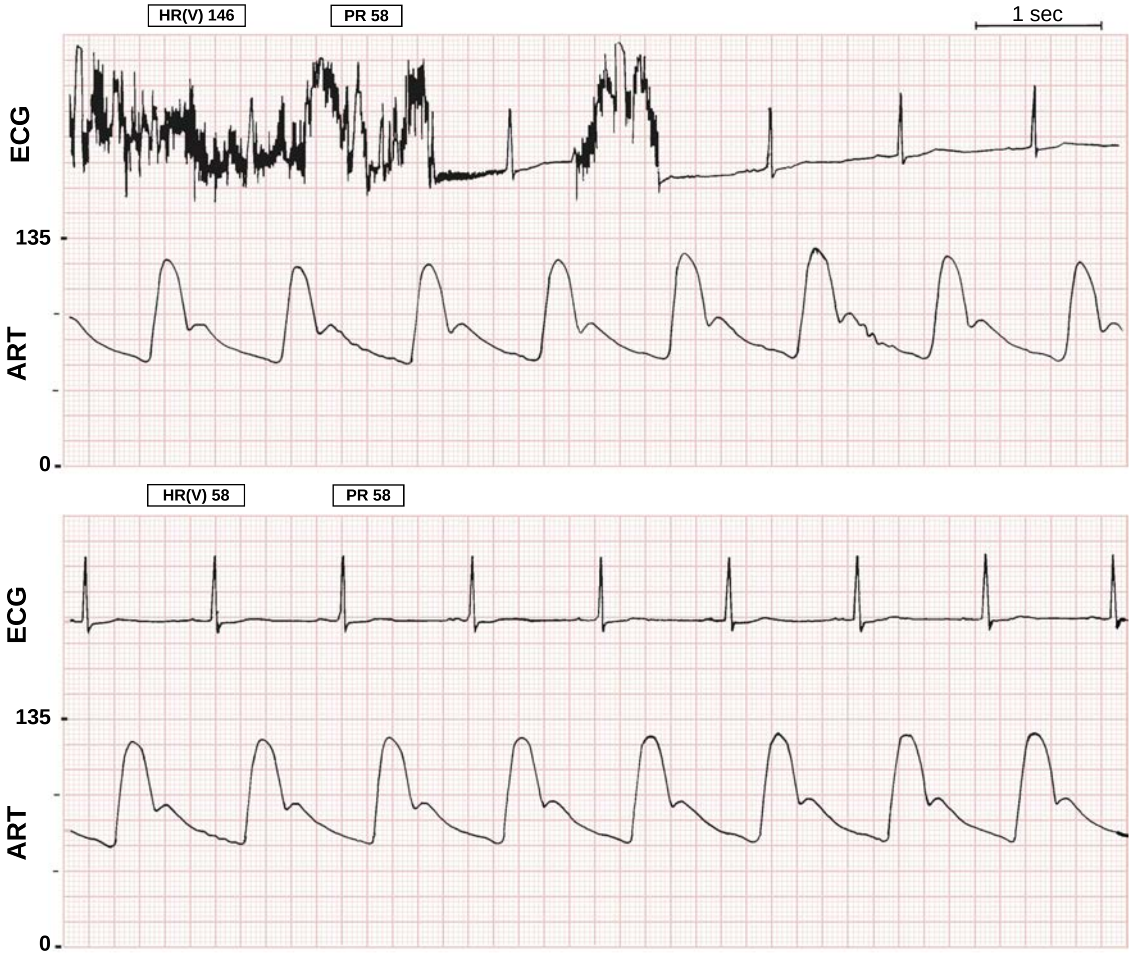

Fig. 36.12 Electrosurgical unit interference with heart rate measurement from the ECG. *(Top panel)* The ECG signal from lead V is distorted by the electrosurgical unit. As a result, the digital value for heart rate *(HR)* is erroneous (146 beats/min), although the pulse rate *(PR)* is measured accurately by the monitor from the arterial blood pressure waveform (58 beats/min). *(Lower panel)* Correct (and identical) digital values for both HR and PR are displayed by the monitor. *ART*, Arterial blood pressure. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

ECG leads (see Fig. 36.11), but other recording systems may provide larger formats for multi-lead or multi-waveform recording. Monitoring systems may also have "full disclosure" capability whereby monitored ECG (and other) waveforms are stored for up to 24 hours and can be retrieved and printed for review. This last system is particularly useful for the retrospective identification, interpretation, and documentation of arrhythmias or other cardiovascular changes that may have escaped detection in real time by clinicians at the bedside.

The ECG tracing on the bedside monitor can be displayed at varying sweep speeds, but most typically is displayed at 25 mm/s, the same speed as a standard 12-lead ECG tracing. As described previously, the ECG gain can be adjusted and the displayed gain should be indicated by a vertical marker overlying the ECG tracing, the standard being 10 mm/mV.

Paper recordings of the ECG should have standard millimeter grids, such that with a standard sweep speed of 25 mm/s, each 1 mm is a 40 ms interval, and a darker line appearing every 5 mm indicates a 200 ms interval (see Fig. 36.11). As noted, the recorded gain is indicated by a 1 mV rectangular calibration signal, the standard being 10 mm/mV.

ELECTROCARDIOGRAM ARTIFACTS

As is the case for all bedside monitoring,[20] artifacts commonly distort the monitored ECG tracing and must be identified to prevent misinterpretation or inappropriate treatment. In the operating room, the most common cause of ECG artifact is the electrosurgical unit (ESU). Since some of the frequencies generated by the ESU fall within the QRS frequency range, and the amplitude of these signals can be very high (1 kV or 1 million times the typical QRS amplitude of 1 mV),[21] even the best current advanced filtering techniques cannot eliminate this artifact that often totally masks the ECG signal (Fig. 36.12). This not only precludes identification of any ECG waveform features, but it can also prevent ECG monitoring of heart rate. The almost universal availability of additional simultaneously displayed waveforms, such as the pulse oximetry plethysmogram or an arterial blood pressure waveform, allow safe patient monitoring during these brief periods of ESU deployment (Fig. 36.12).

Other common ECG artifacts have been identified, and include common sources such as the 60 Hz interference from other medical devices near the patient (see Fig. 36.8B) and less common sources such as the cardiopulmonary

bypass machine.[22] Patel and Souter provide a comprehensive list of reported sources of ECG artifact (Box 36.1).[23]

ELECTROCARDIOGRAM MONITORING FOR MYOCARDIAL ISCHEMIA

The ST segment, representing myocardial repolarization, is the ECG component most sensitive to acute myocardial ischemia. ST elevation, with or without tall positive (hyperacute) T waves, indicates transmural ischemia and is most often the result of acute coronary artery occlusion either by coronary thrombosis or vasospasm (Prinzmetal-variant angina). Reciprocal ST-segment depression may appear in the contralateral leads. Ischemia confined to the subendocardial area is usually denoted by ST-segment depression. Subendocardial, ST-depression–type ischemia typically occurs during episodes of symptomatic or asymptomatic (*silent*) stable angina pectoris, and is characteristic of ischemia occurring during exercise, tachycardia, or pharmacologic stress testing in patients with significant but stable coronary artery disease.

Automated Real-Time ST-Segment Monitoring

Real-time ST-segment analysis first appeared in cardiac monitoring in the mid-1980s and is currently standard in most ECG monitors. On some monitors, the ST-segment analysis is set up to turn on automatically, but while ST-segment analysis is commonplace in the operating room, it is underutilized in other monitoring settings. A recent study has shown that even among coronary care units, less than 50% routinely use ST-segment monitoring for the detection of myocardial ischemia in patients admitted with acute coronary syndromes.[24] Chief among the reasons for the underuse of ST-segment analysis are the frequent number of false alarms and the lack of education on how to use the technology. In addition, no evidence exists as to whether the addition of computerized ST-segment ischemia monitoring improves patient outcomes after surgery.

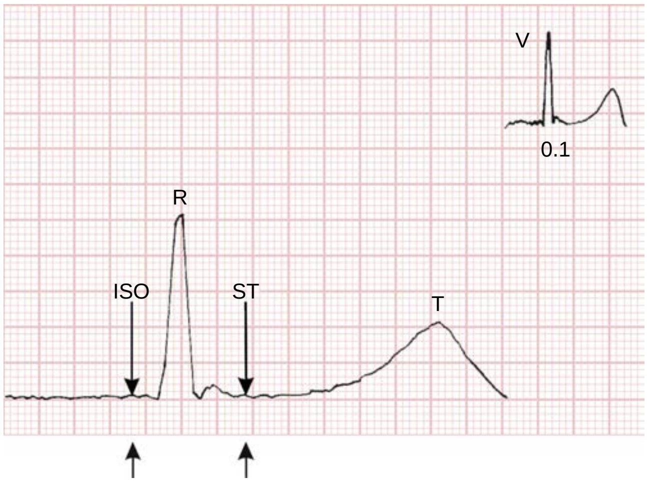

Fig. 36.13 Enlarged display of ECG lead V, showing the isoelectric *(ISO)* and ST-segment *(ST)* measurement points during continuous computer-aided ST-segment monitoring. The ECG R and T waves are also identified. This V lead ECG complex is shown at standard gain (10 mm/mV) in the upper right corner of the panel. The computer measures and displays 0.1 mm (0.01 mV) of ST-segment elevation in this lead. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

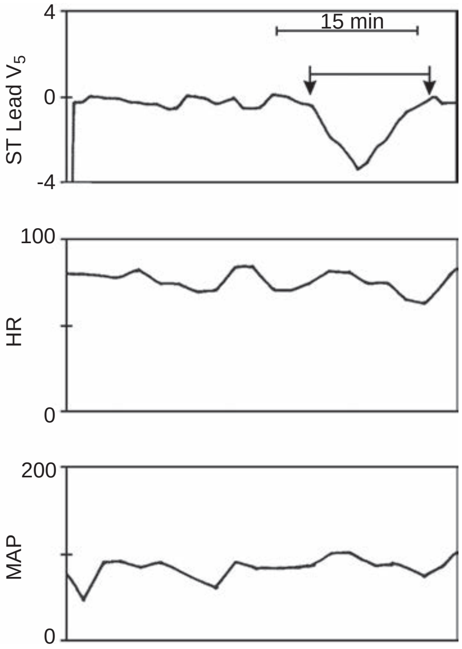

Fig. 36.14 One-hour trend displays for computer-aided continuous ST-segment monitoring in lead V_5, heart rate (*HR*, beats/min), and mean arterial pressure (*MAP*, mm Hg). A 15-minute episode of ST-segment depression *(arrows)* occurs without significant accompanying changes in HR or MAP. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

Computerized ST-segment analysis is achieved by the monitor measuring the ST segment at 60 or 80 ms after the J point (termed as J+60 or J+80 ms) and comparing it with the isoelectric point measured during the PR interval (Fig. 36.13). One millimeter of ST-segment deviation is equivalent to a 0.1 mV difference. The changes in ST-segment level over time in each lead can be displayed as ST-segment trends, just like trend displays of other hemodynamic variables (Fig. 36.14).

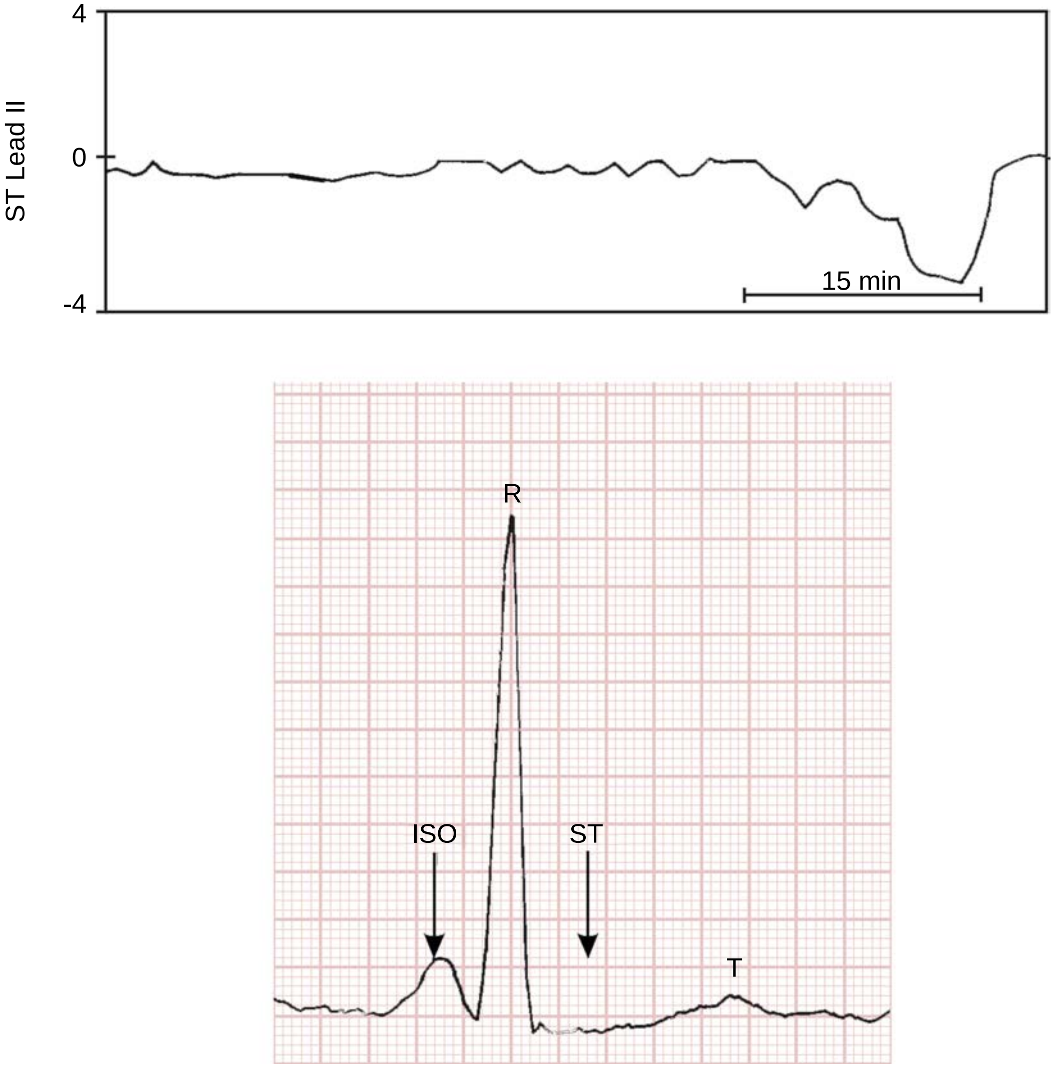

Fig. 36.15 Erroneous identification of the isoelectric *(ISO)* point measurement during computer-aided continuous ST-segment monitoring. A 1-hour trend recording of ST-segment deviations in lead II, displayed as millimeters of ST displacement, shows approximately 15 minutes of ST-segment depression, which reaches 3 mm in magnitude during this episode *(top panel)*. The enlarged display of ECG lead II showing the ISO and ST-segment *(ST)* measurement points during the episode of ST-segment depression reveals that the ISO point is identified inappropriately at the peak of the P wave, thereby producing artifactual ST-segment depression *(bottom panel)*. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

When the computer misidentifies the appropriate isoelectric or ST monitoring point, the clinician can manually adjust the J-point or the ST-segment measurement point (Fig. 36.15).

One major advantage of continuous ST-segment monitoring is that the electrodes stay in place and do not vary as they may with serial 12-lead ECG recordings. However, for improved diagnostic accuracy of ST-segment monitoring, the following points should be recognized:

1. Changes in body position may cause ST-segment changes and lead to false ST-segment alarms. However, changes in the QRS complex almost always accompany these positional ST-segment changes and therefore can be easily distinguished from true ST-segment deviations (Fig. 36.16). Changes in position of the heart in the mediastinum have also shown to affect the ST segment. Mark and associates observed that placement of a sternal retractor during cardiac surgery was associated with a reduction in V_5 R-wave amplitude (Fig. 36.17).[25] Simultaneously, V_5 S-wave amplitude and absolute ST-segment deviation were reduced. These investigators concluded that inclusion of an R-wave gain factor might improve perioperative ECG ischemia monitoring.
2. Many patients have preexisting ECG abnormalities that confound interpretation of ST-segment changes. Early repolarization (a normal variant), intraventricular conduction delays, LV hypertrophy, digitalis, pericarditis, and other conditions may cause baseline ST-segment abnormalities. In these conditions, standard ECG criteria for diagnosing myocardial ischemia are less specific.
3. Most cardiac monitors with ST-segment monitoring software provide displays of ST-segment trends in a single lead or the sum of absolute ST-segment deviations from multiple leads (Fig. 36.18). Although such graphic trends are convenient for the quick identification of potential ischemic events, analysis of the ECG waveform on the monitor screen or by recording the ECG tracing is of paramount importance for verification.

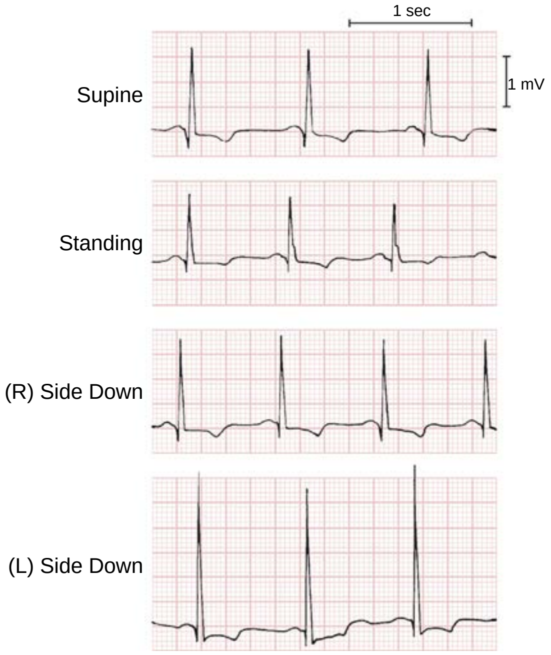

Fig. 36.16 Effect of changing body position on the ECG in a patient with preexisting ST-segment depression. Lead CC_5, a surrogate for lead V_5, is recorded with the patient in four different positions: supine, standing, right *(R)* side down, and left *(L)* side down. The magnitude of ST-segment depression changes in direct proportion to the R-wave amplitude. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

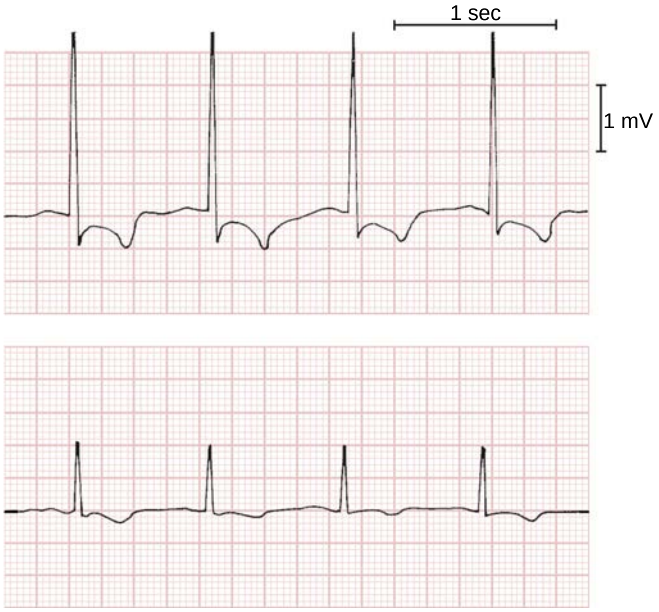

Fig. 36.17 Effect of surgical retraction on the ECG. Baseline lead V_5 recording shows 2 mm ST-segment depression and 27 mm R-wave amplitude *(top panel)*. Placement of a sternal retractor during cardiac surgery displaces the precordial lead electrode relative to the heart, resulting in a marked reduction in R-wave amplitude to 10 mm and a proportional reduction in the magnitude of ST-segment displacement *(bottom panel)*. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

Electrocardiogram Criteria for Acute Myocardial Ischemia

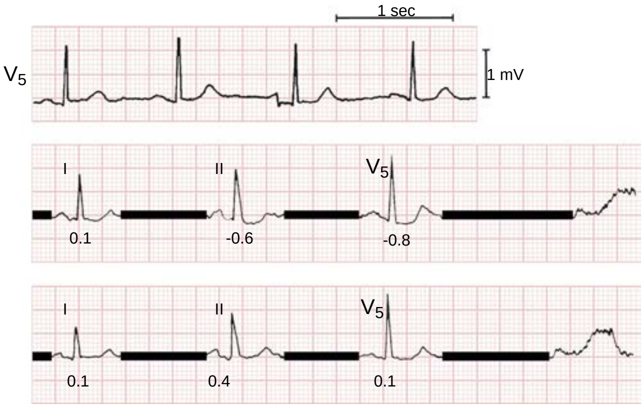

Fig. 36.18 Computer-aided continuous ST-segment monitoring. A baseline recording of lead V_5 shows isoelectric ST segments *(top panel)*. Shortly after induction of anesthesia, the ST-segment monitoring display shows the three monitored leads I, II, and V_5 and the absolute amount of ST-segment elevation (0.1 mm in lead I) or depression (–0.6 mm in lead II, –0.8 mm in lead V_5) in each lead *(middle panel)*. A trend line is displayed on the right side of the panel and demonstrates that the sum of ST-segment deviations in these three monitored leads has increased and reached a plateau over the previous few minutes. Another ST-segment display recorded 5 minutes later shows resolution of these subtle ST changes *(bottom panel)*. Note that the appearance of lead V_5 in this last display closely resembles the baseline recording and that the trend line has returned to pre-induction baseline level. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

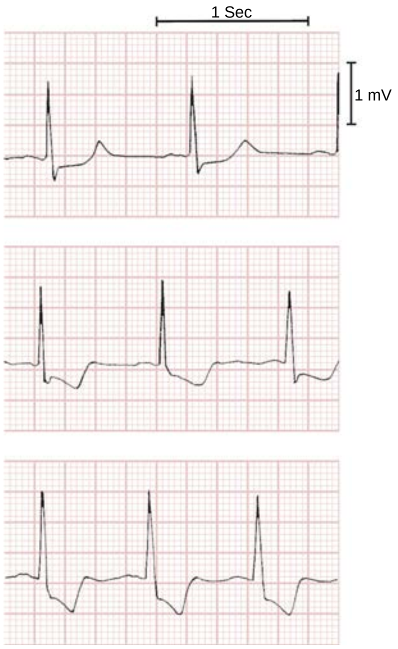

Fig. 36.19 Subendocardial ischemia produces ST-segment depression. As heart rate increases progressively from 63 beats/min *(top panel)* to 75 beats/min *(middle panel)* and finally to 86 beats/min *(bottom, panel)* in this patient with left main coronary artery disease, the ST segment becomes more depressed and more downsloping, owing to an increase in myocardial oxygen demand. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

The ECG criteria most accepted for detecting myocardial ischemia during continuous ECG monitoring are those established and validated during exercise stress testing.[26] During stress testing and with acute subendocardial ischemia, the electrical forces responsible for the ST segment are deviated toward the inner layer of the heart, causing ST-segment depression or demand-mediated ischemia (Fig. 36.19). With acute transmural epicardial ischemia, the electrical forces in the ischemic area are deviated toward the outer layer of the heart, causing ST-segment elevation or supply-mediated ischemia in

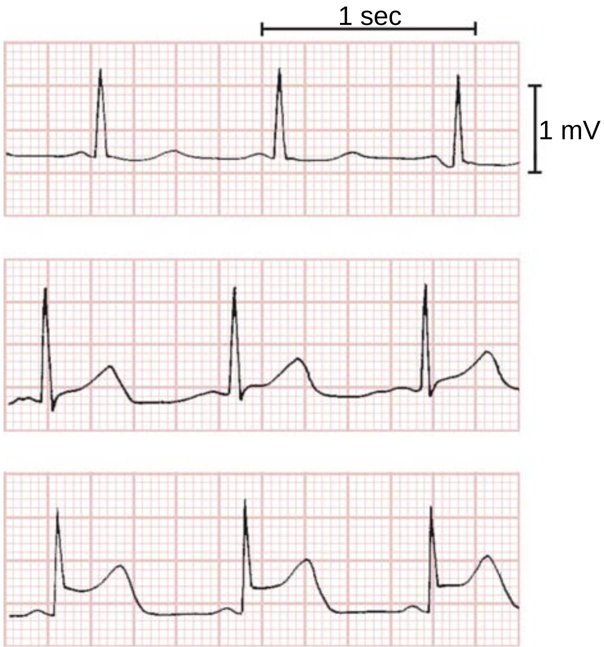

Fig. 36.20 Transmural ischemia produces ST-segment elevation. Occlusion of a patent saphenous vein graft during repeat coronary artery bypass surgery causes an abrupt reduction of coronary blood supply and results in progressive ST-segment elevation *(middle and bottom panels)*. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone;1998.)

the overlying leads (Fig. 36.20). Note that most commonly, intraoperative or perioperative ischemia is demand-mediated subendocardial ischemia, which is manifest as ST-segment depression.[27] Although the anterolateral precordial leads are most sensitive for detecting these changes, they are **non-localizing** as to the coronary distribution responsible. In contrast, supply-mediated transmural ischemia, while much less common perioperatively, causes ST-segment elevation in leads overlying the involved coronary bed and thus are able to **localize** the responsible coronary territory (e.g., ST elevations in inferior leads II, III, aVF suggest occlusion of the right or posterior descending coronary artery).

With demand-mediated ischemia, as heart rate increases, J-point depression and upsloping ST-segment depression occurs. As the severity of ischemia progresses, the ST segment typically becomes horizontal (flattens) and the extent of ST-segment depression may increase and the ST segment may become downsloping (see Fig. 36.19). Standard criteria for stress-induced ischemia are 1 mm (0.1 mV) or more of horizontal or downsloping ST-segment depression measured 60 to 80 ms after the J point. As noted earlier, patients with preexisting ST-segment abnormalities make ST-segment interpretation more difficult.

During the perioperative period, ECG monitoring most commonly identifies stress-induced, ST-depression, demand-mediated ischemia, or other causes of supply-demand imbalance such as prolonged or severe hypotension. Such ECG changes do not provide information about the location of the ischemic myocardial area. In contrast, ST-segment elevation indicating transmural or supply-mediated ischemia, observed particularly during cardiac surgery, provides useful information about the myocardial segment and coronary perfusion territory responsible for the ischemic episode. Because the majority of modern patient-monitoring systems do not simultaneously monitor all 12 ECG leads, selecting which chest leads to monitor is of great importance, particularly in noncardiac surgery. During exercise stress testing, investigators have identified leads V_4 and V_5 as the most sensitive leads to detect exercise-induced ischemia (90%-100% sensitivity).[28] London and colleagues studied high-risk patients undergoing noncardiac surgery and showed that the greatest sensitivity for ischemia was obtained with lead V_5 (75%), followed by lead V_4 (61%).[15] Combining leads V_4 and V_5 increased the sensitivity to 90%, whereas with the standard lead II and V_5 combination, the sensitivity was only 80%. They also suggested that if three leads (II, V_4, and V_5) could be simultaneously examined, the sensitivity would increase to 98%. More recently, Landesberg and associates monitored continuous 12-lead ST-segment changes greater than 0.2 mV from baseline in a single lead or more than 0.1 mV in two contiguous leads at J+60 ms, lasting longer than 10 minutes in patients undergoing major vascular surgery.[16] They showed that leads V_3 and V_4 were more sensitive than V_5 in detecting perioperative ischemia (87%, 79%, and 66%, respectively). As a result of these and other investigations, it appears most appropriate to monitor lead V_3, V_4, or V_5 for optimal detection of perioperative ST-segment depression, choosing the specific lead location based on whether the lead placement might interfere with the surgical prep and procedure.

Blood Pressure Monitoring

Like heart rate, blood pressure has long been a fundamental cardiovascular vital sign included in the mandated standards for basic anesthetic monitoring.[29] Measuring blood pressure is primarily performed with either indirect cuff devices or direct arterial cannulation with pressure transduction. These techniques measure different physical signals and differ in their degree of invasiveness, but both are subject to numerous confounding factors that often result in significant discrepancies among simultaneous measurements.[30]

INDIRECT MEASUREMENT OF ARTERIAL BLOOD PRESSURE

Manual Intermittent Techniques

Most indirect methods of blood pressure measurement utilize a sphygmomanometer, first described by Riva-Rocci in 1896.[31] The systolic pressure was identified using an inflatable elastic cuff around the arm and a mercury manometer to measure cuff pressure, while the radial arterial pulse was palpated as the cuff pressure was increased or rapidly decreased. The technique was later modified to detect both systolic and diastolic pressure with description of auscultatory method of blood pressure measurement by Korotkoff in 1905.[32] Korotkoff sounds are a complex series of audible frequencies produced by turbulent flow beyond the partially occluding cuff. Put simply, the systolic pressure is associated with first sound heard (beginning of turbulent flow through the vessel) and diastolic pressure at the point when the sounds disappear (when vessel flow becomes laminar).[33] Mean blood pressure cannot be measured using this technique.

A fundamental principle of the auscultatory method is its reliance on blood flow to generate Korotkoff sounds. Physiologic conditions that interfere with sound detection (e.g., severe edema, obesity, abnormal compliance of overlying tissue) or blood flow (shock, intense vasoconstriction) will frustrate manual blood pressure measurement.[33-37] Furthermore, the cuff must also be snugly fitted, with a bladder that measures 40% of arm circumference and 80% of length of the upper arm, and centered over the artery. A cuff that is too large will often yield acceptable results when used for *manual* measurements, but a small cuff will usually yield falsely high readings.[36]

Automated Intermittent Techniques

Automated noninvasive blood pressure (NIBP) devices are the most commonly used means of measuring blood pressure in the operating room. Small oscillations in pressure amplitude are measured in an air-filled cuff that slowly deflates from a pressure well in excess of that needed to collapse the underlying artery. The point of maximal oscillation marks the mean arterial blood pressure (MAP), with systolic and diastolic being calculated by various proprietary algorithms specific to individual device manufacturers.[33,35,36] In general, a cuff that is too large will underestimate the blood pressure while a small cuff will overestimate.[36,38] Of the three possible measurements, systolic has the poorest agreement with invasive blood pressure values.[38,39]

Although automated NIBP measurements have generally been shown to approximate directly measured arterial pressures, there are also important shortcomings to keep in mind.[36,38] For reasons involving the ethics of validation against invasive measurements, standards for device performance established by the Association for the Advancement of Medical Instrumentation (AAMI) and the British Hypertension Society are defined by auscultation.[40] New devices must demonstrate average differences ≤ ± 5 mm Hg and standard deviations ≤ 8 mm Hg, which means that deviations of up to 20 mm Hg are still considered "acceptable performance."[41]

Clinical studies comparing NIBP with direct arterial pressure measurements reflect the problematic nature of NIBP monitoring. Direct comparisons of oscillometric devices to invasive monitoring have shown that mean blood pressure measurements generally show the greatest degree of agreement with invasive blood pressure readings while systolic measurements are the most divergent.[39,42-44] Agreement is especially problematic in critically ill or older patients.[38,42-44]

Oscillometric NIBP values tend to underestimate MAP values during periods of hypertension and overestimate during hypotension, potentially biasing clinical decisions in unstable patients.[45] And they often underestimate the systolic while overestimating the diastolic measurements.[46] A well-fitted arm cuff does appear to be helpful in identifying hypotension in unstable patients and differentiating responses to therapy in such situations, but below a MAP of 65 mm Hg, it is not useful for titration of therapy, and a more frequent interval of measurement is probably required to be considered reliable.[38,42,47,48] Dysrhythmia may also result in significant error in blood pressure measurement, especially in systolic and diastolic estimation, although averaging three measurements seems to minimize the clinical impact.[49,50]

While the upper arm is the most common cuff location, various factors may force choice of an alternative site. In obese patients, there is little agreement between any alternate location and invasively measured pressures while ankle, calf, and thigh cuffs have never been validated at all.[51] Interestingly, the forearm may be a preferable site to upper arm in obese patients, although such cuffs display a reversed pattern of bias; overestimation of the systolic and underestimation of the diastolic pressure.[48]

It is important to remember the auscultatory method measures the systolic and diastolic pressures while oscillometric devices measure the mean and calculate the systolic and diastolic, albeit in different and non-interchangeable ways. Furthermore, directly-measured arterial pressure measurements utilize another technique altogether. In some authors' opinions, "current protocols for validating blood pressure monitors give no guarantee of accuracy in clinical practice."[40,52] Expecting them to yield identical values is unrealistic, especially in complex and unstable clinical situations. The sources of error vary significantly for each of these measurement techniques and should closely guide evaluation and therapeutic intervention, especially when there is discrepancy between the measured values or between measurements and clinical conditions.

BOX 36.2 **Complications of Noninvasive Blood Pressure (NIBP) Measurement**

Pain
Petechiae and ecchymoses
Limb edema
Venous stasis and thrombophlebitis
Peripheral neuropathy
Compartment syndrome

Complications of Noninvasive Blood Pressure Measurement

Although automated NIBP measurement is generally safe, there have been reports of rare but severe complications (Box 36.2).[53] Compartment syndrome is possible after prolonged periods of frequent cycling and is most likely related to trauma or impaired distal limb perfusion. Caution should be exercised in cases of peripheral neuropathy, arterial or venous insufficiency, severe coagulopathies, or recent use of thrombolytic therapy.

Automated Continuous Techniques

Continuous methods for NIBP monitoring are being developed with various degrees of success. The most current version is based on the volume clamp technique and involves photoplethysmography and closed loop continuous control of a pressure cuff around a finger. This creates a stable arterial pressure waveform via quantification of an infrared beam applied distal to the finger cuff. Many of these require initial calibration with a standard NIBP

cuff, and all are significantly affected by changes in vascular tone and perfusion in the finger, as well as movement, vascular disease, and a host of other factors.[54] While none of these devices technically meet AAMI standards when compared with invasive pressures, clinical studies have shown their correlation to be reasonable in a variety of operative cases.[35,55-58]

Other devices use technologies related to pulse transit time or arterial tonometry.[59,60] All of these techniques, however, have limitations, including need for calibration, sensitivity to motion artifact, and limited applicability in critically ill patients.[36,61,62] It remains unclear whether any noninvasive technique will reduce the need for direct arterial pressure monitoring during anesthesia or critical care, but with continued development and technical refinement, they remain promising.

DIRECT MEASUREMENT OF ARTERIAL BLOOD PRESSURE

Arterial cannulation with continuous pressure transduction remains the accepted reference standard for blood pressure monitoring despite its risk, cost, and need for technical expertise for placement and management (Box 36.3). Its superiority over noninvasive techniques for early detection of interoperative hypotension was confirmed by The Australian Incident Monitoring Study of 1993.[42,63] More recently, though, the use of waveform analysis in physiologic monitoring has become more popular. This was initially proposed more than a half century ago by Eather and associates, who advocated monitoring of "arterial pressure and pressure pulse contours" in anesthetized patients.[64] Arterial pressure waveform characteristics used in current clinical practice include the dicrotic notch as a trigger for intra-aortic balloon counterpulsation as well as respiratory-induced variation in an array of directly-measured and derived pressure measurements to indicate preload reserve and volume responsiveness.[65-68] Rates of intraoperative direct arterial blood pressure measurement vary significantly across clinical environments even for similar procedures.[69]

Percutaneous Radial Artery Cannulation

The radial artery is the most common site for invasive blood pressure monitoring because it is technically easy to cannulate and complications are rare.[70,71] Slogoff et al. described 1700 cardiovascular surgical patients who underwent radial artery cannulation without ischemic complications despite evidence of arterial occlusion after decannulation in more than 25% of patients.[72] Furthermore, most investigations of hand perfusion following radial artery harvest have reported no significant decrease relative to the contralateral hand in either the early or late postoperative periods.[73-78]

Before radial artery cannulation, some clinicians assess collateral blood flow to the hand by performing a modified Allen test, originally described in 1929 to assess arterial stenosis in patients suffering from thromboangiitis obliterans.[79] The radial and ulnar arteries are both compressed while the patient makes a tight fist to exsanguinate the palm and then slowly reopens it. As occlusion of the ulnar artery is released, the color of the open palm is observed. Normally, the color will return to the palm within several seconds; severely reduced collateral flow is present when the palm remains pale for more than 6 to 10 seconds. Unfortunately, the predictive value of this test is poor. There are numerous reports of ischemic sequelae in the face of a normal Allen test, and conversely, reports of uncomplicated radial catheter use and even harvest for bypass grafting in the presence of an abnormal result.[72,73,80,81] In recent years, the radial artery has become more popular for coronary catheterization and stenting access, even in individuals with abnormal Allen tests.[82] Overall, the diagnostic accuracy of the modified Allen test with a 5-second threshold is only 80% with 76% sensitivity and 82% specificity. It appears that the test is unable to provide a cutoff point below which perfusion can be deemed vulnerable.[83] Use of pulse oximetry, plethysmography, or Doppler ultrasound as adjuncts does not seem to improve its accuracy. Oximetry detects blood flows at extremely low flows, leading to poor specificity, while there are no established ultrasound criteria by which to evaluate radial or ulnar blood flow.[73,84,85] In general, it seems that while a normal modified Allen test may be useful in identifying patients unacceptable for radial artery use for bypass graft or coronary angiography, there is no evidence that it predicts clinical outcomes following cannulation for blood pressure monitoring.[73]

Techniques for radial artery cannulation have been unchanged for decades with the notable exception of the use of ultrasound in guiding catheter placement. Evidence supports its use, especially as a rescue method following a failed attempt.[86] Although evidence in the critical care setting suggests that ultrasound techniques improve first-pass cannulation success rates, it is not clear that this translates to improved clinical outcomes, nor that the impact on time required to perform the procedure or other factors warrants routine intraoperative use.[87-90] Ultrasound guidance in catheterization of other vessels other than the radial artery or in special populations, such as those on mechanical support without pulsatile flow, is more likely to be of substantial benefit.[91]

Alternative Arterial Pressure Monitoring Sites

If the radial arteries are unsuitable or unavailable, there are multiple alternatives. The *ulnar artery* has been used safely even following failed attempts to access the ipsilateral radial artery.[72,92] Similarly, the *brachial artery*, while lacking collateral branches to protect the hand, has a long track record of safe use. Several investigators have reported large series of brachial artery catheters in patients undergoing cardiac surgery with very few vascular, neurologic, or thrombotic sequelae.[93,94] The *axillary artery* has the advantages of patient comfort and mobility, and complications appear to be similar in incidence to those for radial and femoral

BOX 36.4 Complications of Direct Arterial Pressure Monitoring

Distal ischemia, pseudoaneurysm, arteriovenous fistula
Hemorrhage
Arterial embolization
Infection
Peripheral neuropathy
Misinterpretation of data
Misuse of equipment

arteries.[71] A slightly longer catheter is preferred for the brachial or axillary sites due to their relatively deeper and more mobile anatomic locations. Clinicians should be aware, however, that the risk of cerebral embolization is significantly increased when more central vessels are utilized.

The *femoral artery* is the largest vessel in common use for blood pressure monitoring but its safety profile seems comparable to other sites.[71] Catheterization of the femoral artery is best achieved with a guidewire technique and the point of vessel entry must be distal to the inguinal ligament to minimize the risk of arterial injury, hidden hematoma formation, or even uncontrolled hemorrhage into the pelvis or retroperitoneum.[95]

Less commonly used alternatives include the *dorsalis pedis, posterior tibial*, and *superficial temporal arteries*, with the pedal vessels being more popular in pediatric patients. Lower extremity vessels tend to demonstrate greater with disagreement noninvasively acquired data, with diastolic and mean measurements being the most affected.[96]

Complications of Direct Arterial Pressure Monitoring

Although large clinical investigations confirm the low incidence of long-term complications after radial arterial pressure monitoring, factors that may increase such risks include vasospastic arterial disease, previous arterial injury, thrombocytosis, protracted shock, high-dose vasopressor administration, prolonged cannulation, and infection.[70-73,97,98]

Rare but serious complications have been reported after arterial cannulation at all locations (Box 36.4). In most cases, catheter placement was technically difficult or there were contributory factors such as shock or coagulopathy. In a large observational study of 2000 untoward clinical events resulting from any kind of vascular access, only 13 were related to peripheral arterial cannulation, fewer than those associated with central venous (18) or even peripheral venous cannulation (33). The events involved equipment problems, inadvertent drug administration, or disruption/kinking of the catheter itself. In only 1 case did transient vasospasm follow radial artery cannulation. An additional 10 cases were noted to involve problems with incorrect device calibration or erroneous data interpretation.[63,99] Data from the anesthesia closed claims reports have shown that claims related to arterial pressure monitoring constitute only 8% of all claims related to any vascular access (2% of total claims). Of this small number, almost 54% were related to radial artery use (ischemic injury, median or radial nerve injury, or retained wire fragment), less than 8% were associated with use of the brachial artery, and the remainder involved severe thrombotic or hemorrhagic complications following femoral artery monitoring.[100] While patient physiology is important, equipment misuse, poor placement technique or catheter care, as well as improper data interpretation play important roles in most complications related to arterial pressure monitoring.

Technical Aspects of Direct Blood Pressure Measurement

There are a variety of factors, including extension tubing, stopcocks, flush devices, recorders, amplifiers, and transducers that may confound the process by which pressure waveforms are reproduced for measurement and display.[101]

Most invasive blood pressure monitoring systems are underdamped second-order dynamic systems that demonstrate simple harmonic motion dependent on *elasticity, mass*, and *friction*.[101-103] These three properties determine the system operating characteristics (i.e., *frequency response* or *dynamic response*) which in turn are characterized by *natural frequency* and *damping coefficient*. The natural frequency of a system determines how rapidly the system oscillates after a perturbation, while the damping coefficient reflects how rapidly it returns to its prior resting state. Both parameters may be estimated or measured at the bedside and dramatically influence the appearance of the displayed pressure waveform.

Natural Frequency, Damping Coefficient, and Dynamic Response of Pressure Monitoring Systems

The displayed pressure waveform is a periodic complex wave produced via Fourier analysis of a summation of multiple propagated and reflected pressure waves. As such, it is a mathematical re-creation of the original complex pressure wave created and propagated by stroke volume ejection.[104,105] The original pressure wave is characterized by its fundamental frequency, a characteristic manifested clinically as the pulse rate and expressed as cycles/second (Hertz).

The sine waves that sum to produce the final complex wave have frequencies that are multiples or harmonics of the fundamental frequency (i.e., pulse rate). A very crude arterial waveform depicting a systolic upstroke and peak, dicrotic notch, and so forth can be reconstructed with reasonable accuracy from only two sine waves, the fundamental frequency and the second harmonic (Fig. 36.21). As a general rule, though, 6 to 10 harmonics are required to provide distortion-free reproductions of most arterial pressure waveforms.[104,106] Consequently, accurate blood pressure measurement in a patient with a pulse rate of 120 beats/min (2 cycles/s or 2 Hz) requires a monitoring system dynamic response of 12 to 20 Hz (i.e., 6 to 10 waveforms X 2 Hz). The faster the heart rate and the steeper the systolic pressure upstroke, the greater the demands on the monitoring system.

Natural frequency and damping coefficient are intrinsic characteristics of all monitoring systems. If the system's natural frequency is too low, the system will resonate, and pressure waveforms recorded on the monitor will be exaggerated or amplified versions of true intraarterial pressure. An underdamped system may combine elements of the measurement system itself with the measured sine waves

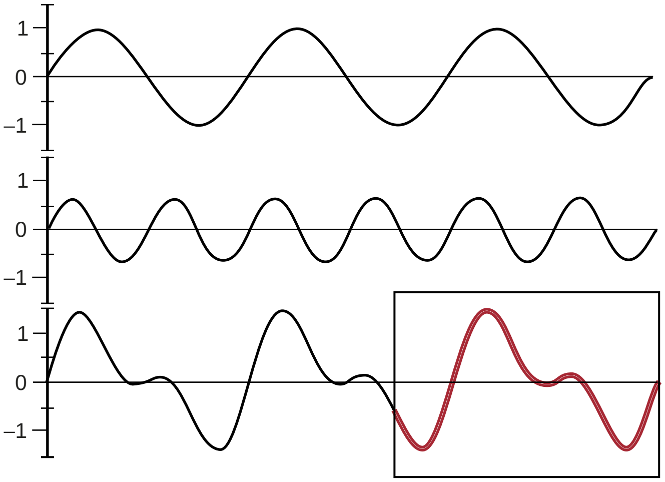

Fig. 36.21 Arterial blood pressure waveform produced by summation of sine waves. The fundamental wave *(top)* added to 63% of the second harmonic wave *(middle)* results in a pressure wave *(bottom)* resembling a typical arterial blood pressure waveform *(box)*. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

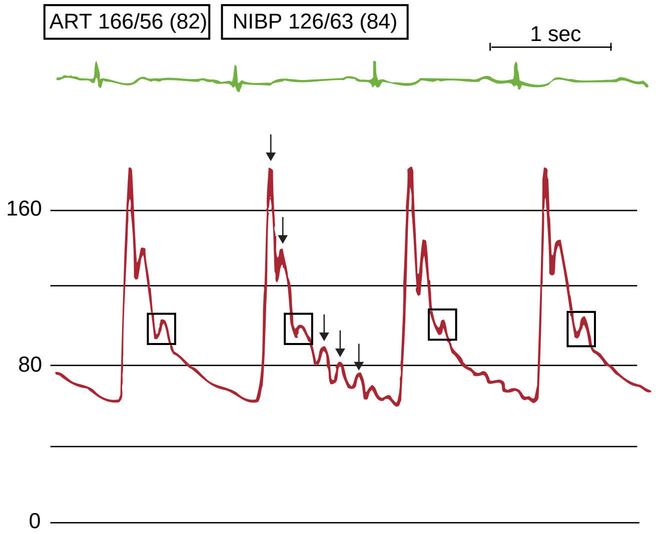

Fig. 36.22 Underdamped arterial pressure waveform. Systolic pressure overshoot and additional small, nonphysiologic pressure waves *(arrows)* distort the waveform and make it hard to discern the dicrotic notch *(boxes)*. Digital values displayed for direct arterial blood pressure (*ART* 166/56, mean 82 mm Hg) and noninvasive blood pressure (*NIBP* 126/63, mean 84 mm Hg) show the characteristic relationship between the two measurement techniques in the presence of an underdamped system. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

and display systolic pressure overshoot (Fig. 36.22). In contrast, an overdamped waveform exhibits a slurred upstroke, absent dicrotic notch, and loss of fine detail. In such cases, the pulse pressure will be falsely narrow but MAP may remain reasonably accurate (Fig. 36.23).

The interplay between natural frequency and damping coefficients is complex, but in general, the lower the natural frequency of the system, the narrower the range of acceptable damping coefficients. It follows logically that for any specific system, the highest possible natural frequency yields the optimal result.[105] In theory, this is best achieved by using short lengths of stiff pressure tubing and limiting

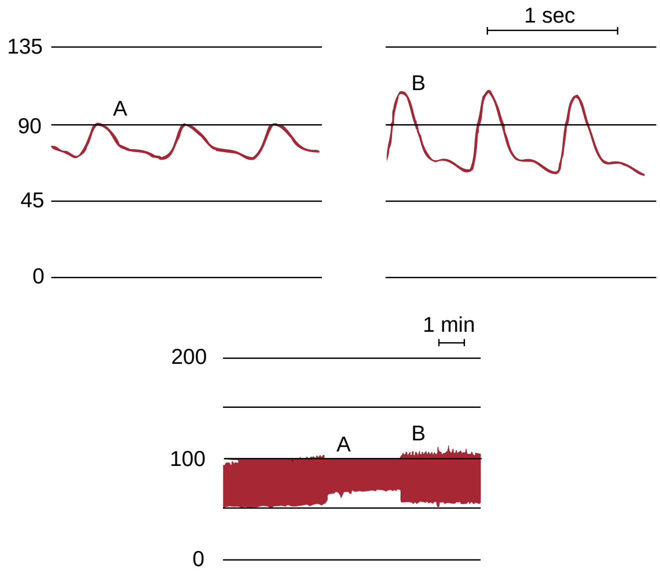

Fig. 36.23 Overdamped arterial pressure waveform. The overdamped pressure waveform (A) shows a diminished pulse pressure compared with the normal waveform (B). The slow-speed recording *(bottom)* demonstrates a 3-minute period of damped arterial pressure. Note that despite the damped system, mean arterial pressure remains unchanged. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

additions or connections to the system such as stopcocks. While adding an air bubble to the monitoring system will increase damping, it simultaneously lowers natural frequency and may actually increase the intrinsic system resonance and worsen systolic pressure overshoot (Fig. 36.24).

The fast-flush test provides a convenient bedside method for determining system dynamic response and assessing signal distortion.[101,103,105] The nature and duration of the flush artifact following a brief opening of the fast-flush valve are noted visually with shorter oscillation cycles indicating a higher natural frequency and the damping coefficient being related to the resulting pattern of peak amplitudes (Fig. 36.25).[101,105] Thus, an adequate fast-flush test pattern has short oscillation cycles (<30 ms) and a pattern of amplitudes that rapidly return to rest. The clinical impact of resonance and under- or over-damping is common, occurring in up to 30% of surgical patients and 44.5% of patients admitted to the ICU. Interestingly, it appears to be more significant for systolic blood pressure measurement than mean or diastolic, and is associated with preexisting arteriopathy, lung disease, hypertension, and smaller-gauge arterial catheters.[107] Distortion of the arterial waveform is common in clinical practice, particularly systolic pressure overshoot secondary to underdamped systems.[101,108]

Pressure Monitoring System Components

Arterial pressure monitoring systems have a number of components, including the intraarterial catheter itself, stopcocks for blood sampling and transducer zeroing, in-line blood sampling ports, a pressure transducer, continuous-flush device, and electronic cable. Innovation to the basic system such as needleless ports and closed aspiration systems, while intended to improve safety, may also degrade the dynamic response of the monitoring system and further exacerbate systolic arterial pressure overshoot.

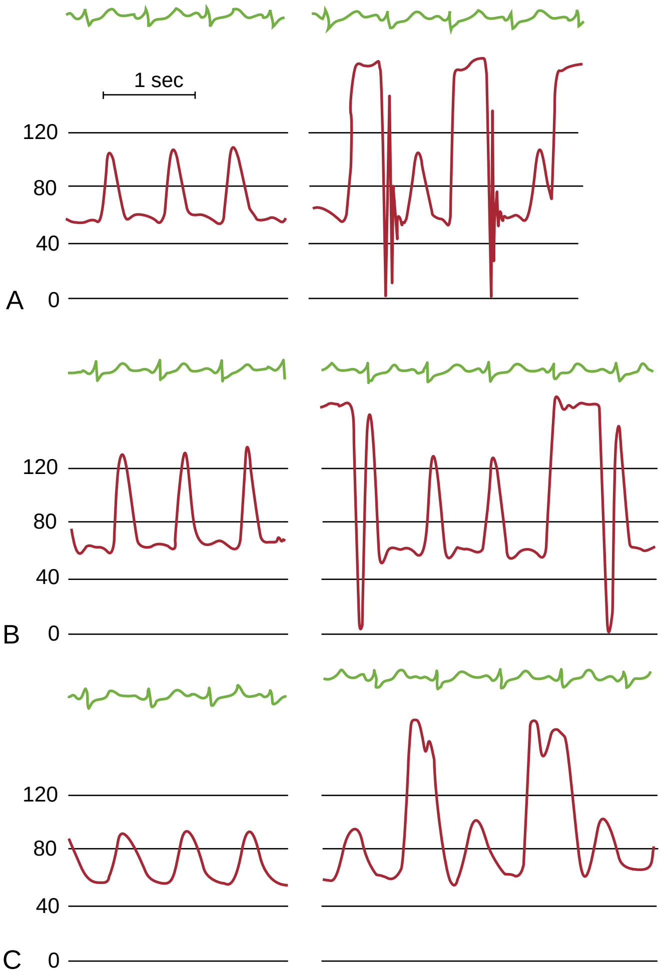

Fig. 36.24 Effect of small air bubbles within arterial pressure monitoring systems. Arterial pressure waveforms are displayed, along with superimposed fast-flush square-wave artifacts. (A) Original monitoring system has an adequate dynamic response (natural frequency 17 Hz, damping coefficient 0.2). (B) A small 0.1-mL air bubble added to the monitoring system produces a paradoxical increase in arterial blood pressure. Note decreased natural frequency of the system. (C) A larger 0.5-mL air bubble further degrades dynamic response and produces spurious arterial hypotension. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

The flush device provides a continuous, slow (1-3 mL/h) infusion of saline to purge the monitoring system and prevent thrombus formation within the system. Dextrose solutions should not be used, since flush contamination of sampled blood may cause serious errors in blood glucose measurement.[109] The flush device not only ensures continuous slow flushing of the system but also includes a spring-loaded valve for periodic, high-pressure flushing following sample collection or to restore the system's dynamic response to baseline.[110]

Transducer Setup: Zeroing and Leveling

Prior to use, pressure transducers must be zeroed, calibrated, and leveled to the appropriate position, a maneuver accomplished by exposing the transducer to atmospheric pressure and performing the zero procedure as defined by each device manufacturer. It is important to recognize that the *zero pressure locus* should be positioned appropriately given the specific clinical context, that it is positioned relative to the patient, that the zero reference point is local atmospheric pressure, and that the zero should be checked and re-zeroed periodically.[105] Occasionally, a faulty transducer, cable, or monitor will cause the zero baseline to drift, introducing significant error until the zero reference is reestablished.[111,112] Because current disposable pressure transducers meet accuracy standards established by the AAMI and the American National Standards Institute, formal bedside transducer calibration is no longer routinely performed. However, it remains good practice to routinely compare pressures obtained via a newly placed arterial catheter with a blood pressure obtained via other means.[111,112]

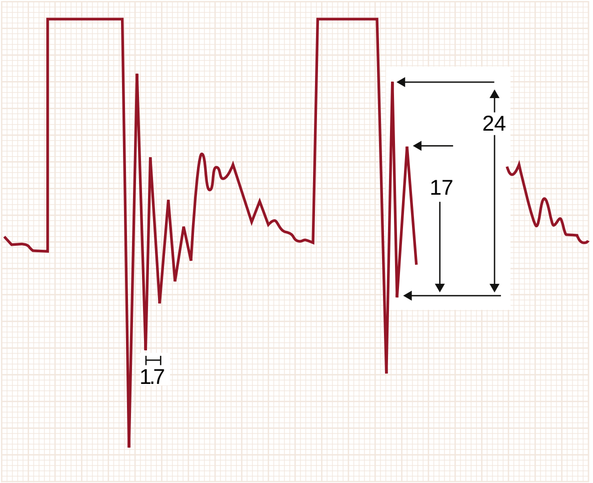

Fig. 36.25 Clinical measurement of natural frequency and damping coefficient. Two square-wave fast-flush artifacts interrupt an arterial pressure waveform recorded on standard 1-mm grid paper at a speed of 25 mm/s. Natural frequency is determined by measuring the period of one cycle of adjacent oscillation peaks (1.7 mm). Damping coefficient is determined by measuring the heights of adjacent oscillation peaks (17 and 24 mm). From these measurements, a natural frequency of 14.7 Hz and an amplitude ratio of 0.71 may be calculated. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

Choosing the appropriate level at which to establish the zero point must be done with respect to the patient and the clinical context. Note that transducer zeroing and leveling are distinct and separate. Zeroing establishes the zero reference point as ambient atmospheric pressure, while leveling aligns this reference point relative to the patient's body, determining where the value "0" will be. This is even more important when monitoring values for which the physiologic range is small, such as central venous or intracranial pressure. In such cases, small zeroing or leveling errors may translate to large relative errors in measurement.

In most cases, arterial pressure transducers should be placed to best estimate aortic root pressure. In general, the best position for this is approximately 5 cm posterior to the sternal border.[113,114] However, a more conventional location for the reference level used for all hemodynamic monitoring, including central venous and pulmonary artery pressures (PAPs), is the mid-thoracic level, which corresponds most closely to the mid-left atrial position and is located halfway between the anterior sternum and the bed surface in the supine patient.[115,116] The most critical point, regardless of where the clinician chooses to assign the reference level, is that it is consistently maintained throughout the monitoring period.

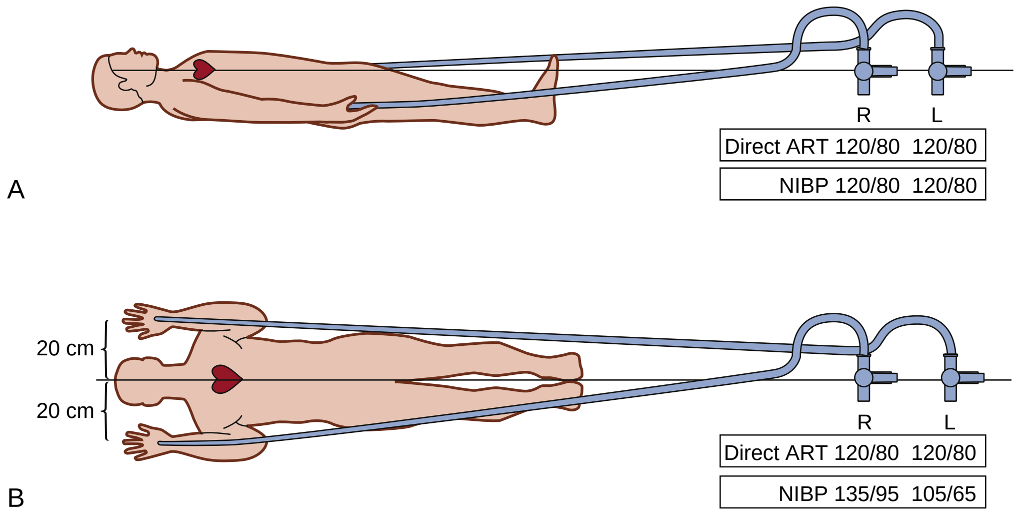

Fig. 36.26 Effect of patient position on the relation between direct arterial blood pressure *(ART)* and indirect noninvasive blood pressure *(NIBP)* measurements. (A) In the supine patient, pressures measured from the right *(R)* or left *(L)* arms by either technique will be the same. (B) In the right lateral decubitus position, ART pressures recorded directly from the right and left radial arteries will remain unchanged so long as the respective pressure transducers remain at heart level. However, NIBP will be higher in the dependent right arm and lower in the nondependent left arm. Differences in NIBP are determined by the positions of the arms above and below the level of the heart and are equal to the hydrostatic pressure differences between the level of the heart and the respective arm. A 20-cm difference in height produces a 15-mm Hg difference in pressure. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York; Churchill Livingstone; 1998.)

In specific circumstances, though, clinicians may choose to place the transducer at a level different from the standard. For example, during a sitting neurosurgical procedure, it may be more informative to place it at the level of the patient's ear to approximate the level of the Circle of Willis. In such cases, the blood pressure at the level of the brain is being measured and displayed rather than that of the aortic root, which will be significantly higher. Fixing the transducer to a pole rather than the bed risks introducing error when the bed height or position is changed.

For proper interpretation of blood pressure measurements from a patient in the lateral decubitus position, differentiating zeroing and leveling pressure transducers and appreciating the differences between noninvasive and invasive blood pressure measurement is an informative exercise. In this position, while the aortic root remains stationary, one arm is necessarily higher than the other. However, as long as the pressure transducer remains *fixed at the level of the heart*, the measured pressure remains completely unaffected by the position of the arms, or location of the arterial catheter. Conversely, non-invasive cuff blood pressure measurements will differ in the two arms, being higher in the dependent (down) arm and lower in the non-dependent (up) arm (Fig. 36.26). This relationship must be taken into account when using the cuff to calibrate an invasively measured pressure.

Normal Arterial Pressure Waveforms

The systemic arterial pressure waveform results from ejection of blood from the left ventricle during systole followed by peripheral runoff during diastole. The systolic waveform immediately follows the ECG R wave and consists of a steep pressure upstroke, peak, and ensuing decline. The downslope of the arterial pressure waveform is interrupted by the dicrotic notch, continues its decline during diastole after the ECG T wave, and reaches its nadir at end-diastole (Fig. 36.27). The dicrotic notch of a central aortic pressure waveform is sharply defined and thought to result from aortic valve closure.[117] In contrast, more peripheral arterial waveforms generally display a slightly delayed and mildly blunted dicrotic notch that is more dependent on properties of the arterial wall. Note that the systolic upstroke starts 120 to 180 ms after beginning of the R wave, reflecting the time required for LV depolarization, isovolumic contraction, opening of the aortic valve, LV ejection, and propagation of the pressure wave through the aorta to the pressure transducer (see Fig. 36.27).

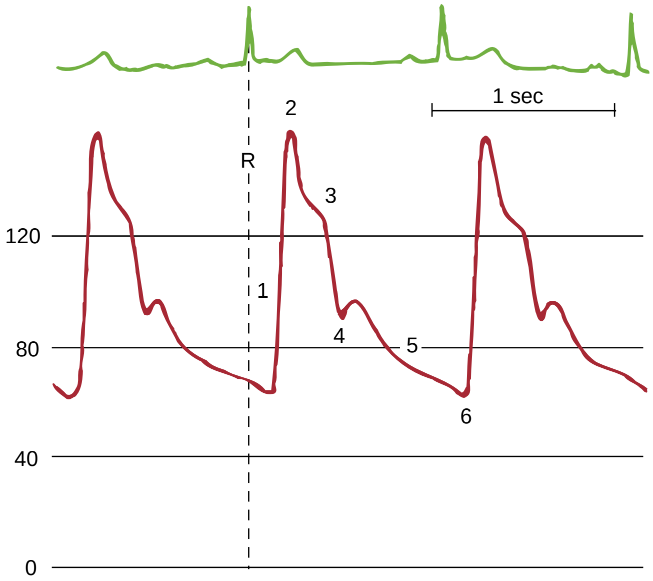

Fig. 36.27 Normal arterial blood pressure waveform and its relation to the electrocardiographic R wave. *(1)* Systolic upstroke, *(2)* systolic peak pressure, *(3)* systolic decline, *(4)* dicrotic notch, *(5)* diastolic runoff, and *(6)* end-diastolic pressure. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

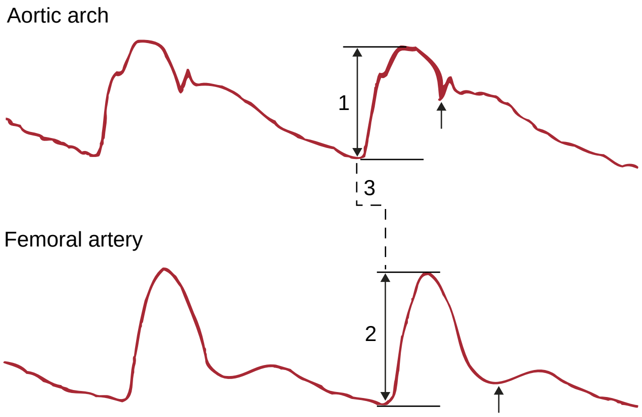

Fig. 36.28 Distal pulse wave amplification of the arterial pressure waveform. Compared with pressure in the aortic arch, the more peripherally recorded femoral artery pressure waveform demonstrates a wider pulse pressure (compare *1* and *2*), a delayed start to the systolic upstroke *(3)*, a delayed, slurred dicrotic notch (compare *arrows*), and a more prominent diastolic wave. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

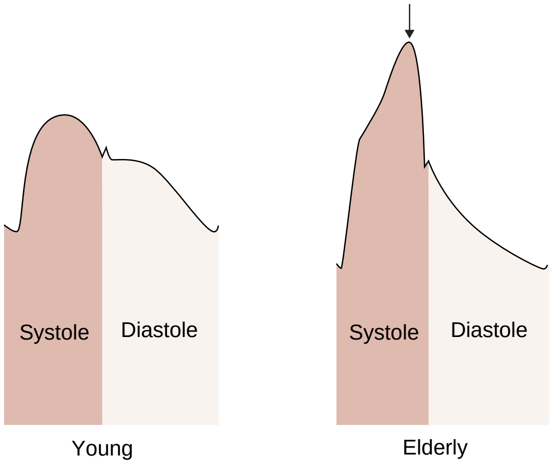

Fig. 36.29 Impact of pressure wave reflection on arterial pressure waveforms. In older individuals with reduced arterial compliance, early return of peripherally reflected waves increases pulse pressure, produces a late systolic pressure peak *(arrow)*, attenuates the diastolic pressure wave, and at times, distorts the smooth upstroke with an early systolic hump.

The bedside monitor displays values for the systolic peak and end-diastolic nadir pressures. In simplest terms, MAP reflects the area beneath the arterial pressure curve divided by the beat period, averaged over multiple cardiac cycles, but is dependent on device-specific algorithms. MAP is sometimes estimated as diastolic pressure plus one third of the pulse pressure but this shortcut is only valid at slower heart rates, because the duration of diastole decreases as the heart rate increases.[118]

The morphology of the arterial waveform and the precise values of systolic and diastolic blood pressure vary throughout the arterial system even under normal conditions in healthy individuals in a variety of ways. Distal pulse amplification is one such example. Pressure waveforms recorded simultaneously from different sites have different morphologies due to the physical characteristics of the vascular tree, namely, impedance and harmonic resonance (Fig. 36.28).[62,119] As the pressure wave travels from the central aorta to the periphery, the arterial upstroke becomes steeper, the systolic peak rises, the dicrotic notch appears later, the diastolic wave becomes more prominent, and end-diastolic pressure falls. As a result, peripheral arterial waveforms have higher systolic, lower diastolic, and wider pulse pressures compared with central aortic waveforms. Interestingly, the displayed MAP is only slight increased.

Reflection of pressure waves within the arterial tree significantly affects the arterial pressure waveform as it travels peripherally.[119] As blood flows from the aorta to the radial artery, MAP decreases only slightly because there is little resistance to flow in the major conducting arteries. At the arteriolar level, though, resistance to flow shrinks pressure pulsations in smaller downstream vessels but augments upstream arterial pressure pulses due to reflected pressure waves.[120] It is the summation of these antegrade and reflected waves that determines the shape of the displayed waveform. For example, reduced arterial compliance causes extremely rapid return of reflected pressure waves, resulting in arterial pressure waveforms with increased pulse pressure, a late systolic pressure peak, attenuated diastolic pressure waves, and at times, an early systolic hump distorting the smooth upstroke (Fig. 36.29).

Arterial Blood Pressure Gradients

Numerous pathophysiologic conditions cause exaggerated arterial pressure gradients between monitoring sites, be they real, iatrogenic, or artifactual. Frank and coworkers found that 21% of patients undergoing peripheral vascular surgery had a blood pressure difference between the two arms that exceeded 20 mm Hg.[121] Atherosclerosis, arterial dissection, stenosis, or embolism may exclude certain locations as reliable sites for invasive monitoring. In addition, certain patient positions, surgical retraction, or clamp placement may compromise perfusion in regional or local areas, precluding specific sites from use for invasive monitoring.[122,123]

Pathologic changes in peripheral vascular resistance may also produce generalized arterial pressure gradients that can affect the choice of site for arterial pressure monitoring. In patients receiving vasopressor infusions for septic shock, the femoral arterial pressure may exceed the radial pressure by greater than 50 mm Hg.[124] Less severe gradients have been noted with general anesthesia, neuraxial blocks, and changes in patient temperature.[62] During hypothermia, vasoconstriction causes systolic pressure in the radial artery to exceed that in the femoral artery, whereas during rewarming, vasodilation reverses the gradient.[125]

Characteristic gradients between central and peripheral sites have also been described during cardiopulmonary bypass (Fig. 36.30). The mean radial artery pressure falls on initiation of bypass and remains lower than mean femoral artery pressure throughout the bypass period and into the initial postbypass period, often by more than 20 mm Hg.[126,127] In most patients, this gradient resolves within the first hour, but occasionally remains well into the postoperative period.

Abnormal Arterial Pressure Waveforms

The morphologic features of individual arterial pressure waveforms can provide important diagnostic information (Table 36.1) (Fig. 36.31A–D). Aortic stenosis produces a

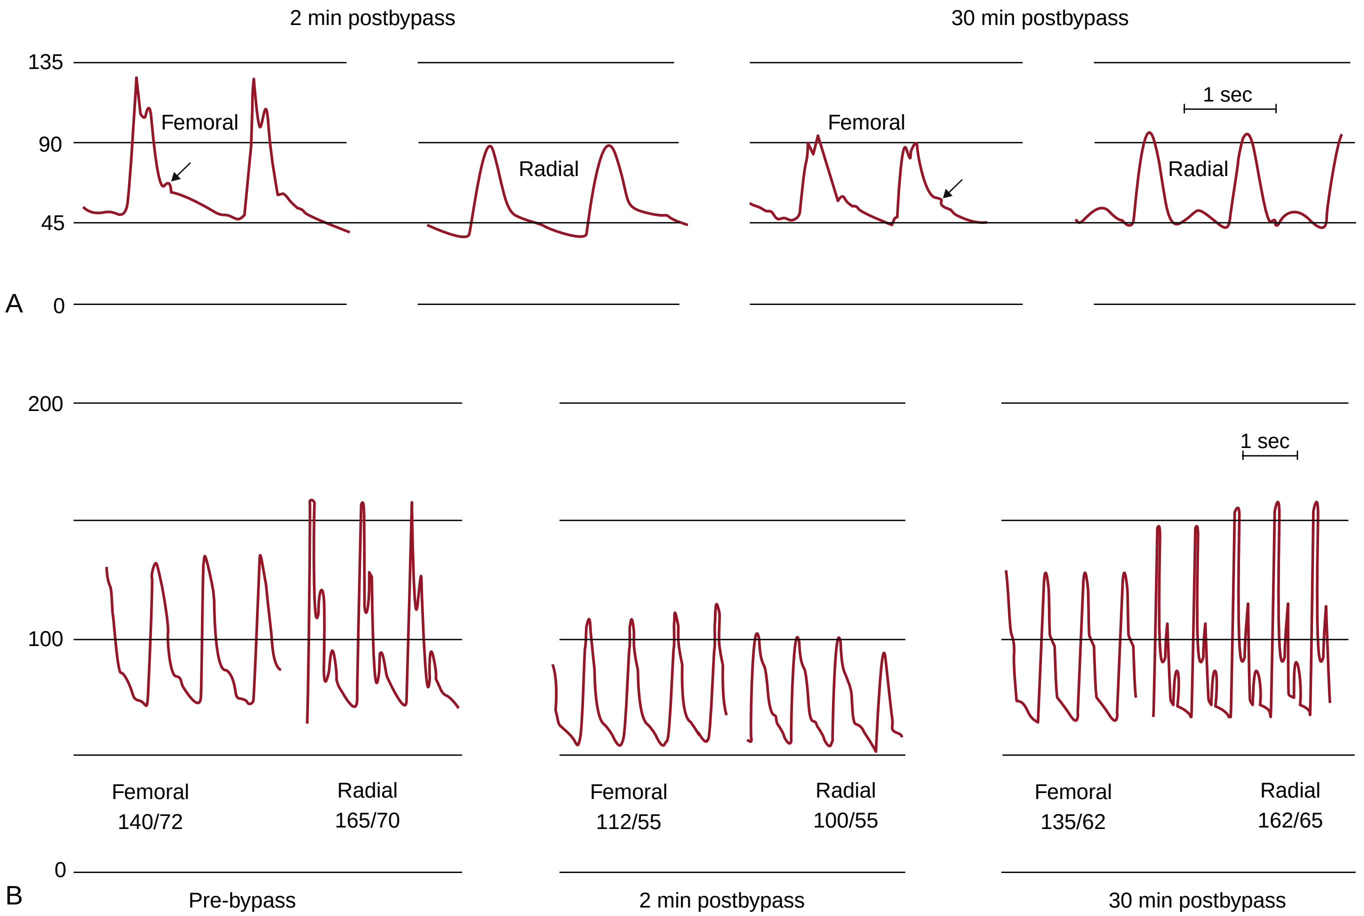

Fig. 36.30 Arterial pressure gradients following cardiopulmonary bypass. (A) Femoral and radial artery pressure traces recorded 2 minutes after bypass (2 min postbypass), when radial artery pressure underestimates the more centrally measured femoral artery pressure and 30 minutes later (30 min postbypass), when radial and femoral arterial pressures have equalized and radial pressure has resumed a more typical morphology. Note that dicrotic notch *(arrows)* is visible in the femoral pressure trace immediately after bypass, but is delayed in the radial pressure trace. (B) Femoral and radial artery pressure traces recorded before cardiopulmonary bypass (pre-bypass), 2 minutes following bypass (2 min postbypass), and 30 minutes following bypass (30 min postbypass). Note changing relationship between femoral and radial artery pressure measurements at these different times.

TABLE 36.1 Arterial Blood Pressure Waveform Abnormalities

Condition	**Characteristics**
Aortic stenosis	Pulsus parvus (narrow pulse pressure) Pulsus tardus (delayed upstroke)
Aortic regurgitation	Bisferiens pulse (double peak) Wide pulse pressure
Hypertrophic cardiomyopathy	Spike and dome (mid-systolic obstruction)
Systolic left ventricular failure	Pulsus alternans (alternating pulse pressure amplitude)
Cardiac tamponade	Pulsus paradoxus (exaggerated decrease in systolic blood pressure during spontaneous inspiration)

fixed obstruction to ejection resulting in reduced stroke volume and a slowed rate of ejection. As a result, the waveform is small in amplitude *(pulsus parvus)*, has a slowly rising systolic upstroke *(pulsus tardus)*, and a delayed peak in systole (see Fig. 36.31B). A distinct shoulder, termed the anacrotic notch, often distorts the pressure upstroke and the dicrotic notch may not be discernible. These features may make the arterial pressure waveform appear overdamped.

In aortic regurgitation, the arterial pressure wave displays a sharp rise, wide pulse pressure, and low diastolic pressure owing to the diastolic runoff of blood both antegrade into the aortic root and retrograde into the left ventricle. The arterial pressure pulse may have two systolic peaks *(bisferiens pulse)*, with the first peak resulting from antegrade ejection and the second from a wave reflected from the periphery (see Fig. 36.31C). In hypertrophic cardiomyopathy, the waveform assumes a peculiar bifid shape termed a "spike-and-dome" configuration. After an initial sharp blood pressure increase resulting from rapid, early systolic ejection, arterial pressure abruptly falls as midsystolic LV outflow obstruction interrupts stroke volume ejection. This is finally followed by a second, late-systolic increase associated with arrival of reflected waves from the periphery (see Fig. 36.31D).

Changes in arterial waveform patterns over time are also valuable. *Pulsus alternans* is a pattern of alternating larger and smaller pressure waves that appear to vary with the respiratory cycle and is generally associated with severe LV systolic dysfunction or aortic stenosis (Fig. 36.32A).

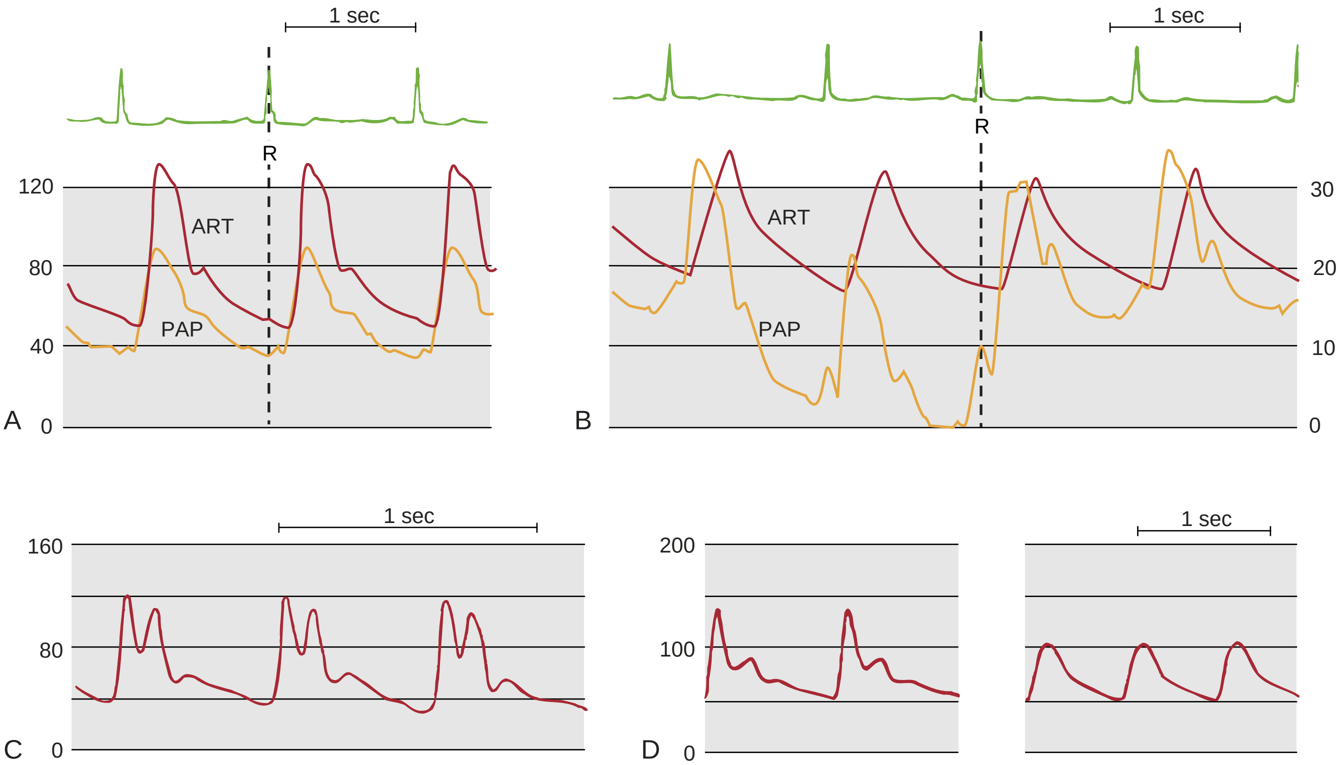

Fig. 36.31 Influence of pathologic conditions on arterial pressure *(ART)* waveform morphology. (A) Normal ART and pulmonary artery pressure *(PAP)* waveform morphologies demonstrating the similar timing of these waveforms relative to the electrocardiographic R wave. (B) In aortic stenosis, the ART waveform is distorted with a slurred upstroke and delayed systolic peak. These changes are particularly striking in comparison with the normal PAP waveform. Note the beat-to-beat respiratory variation in the PAP waveform. For A and B, the ART scale is on the left and the PAP scale is on the right. (C) Aortic regurgitation produces a bisferiens pulse and a wide pulse pressure. (D) Arterial pressure waveform in hypertrophic cardiomyopathy shows a peculiar spike-and-dome configuration. The waveform assumes a more normal morphology following surgical correction of this condition. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

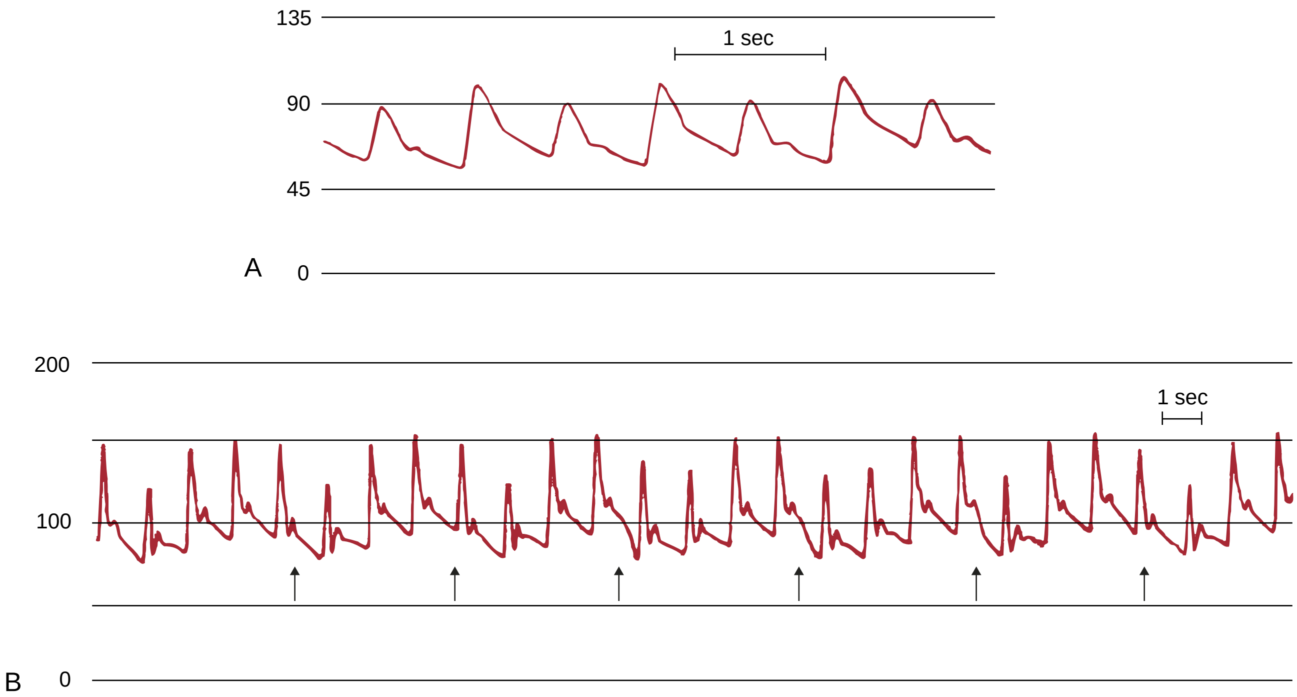

Fig. 36.32 Beat-to-beat variability in arterial pressure waveform morphologies. (A) Pulsus alternans. (B) Pulsus paradoxus. The marked decline in both systolic blood pressure and pulse pressure during spontaneous inspiration *(arrows)* is characteristic of cardiac tamponade. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

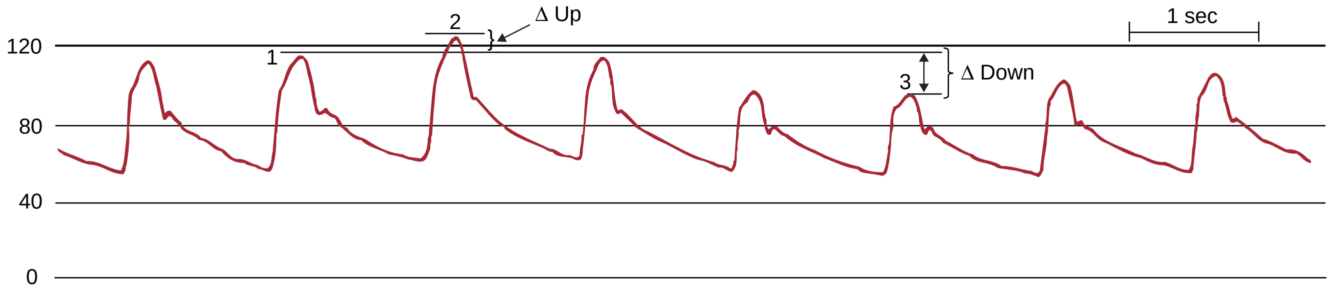

Fig. 36.33 Systolic pressure variation. Compared with systolic blood pressure recorded at end expiration *(1)* a small increase occurs during positive-pressure inspiration (*2*, Δ Up) followed by a decrease (*3*, Δ Down). Normally, systolic pressure variation does not exceed 10 mm Hg. In this instance, the large Δ Down indicates hypovolemia even though systolic arterial pressure and heart rate are relatively normal. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

Pulsus paradoxus is an exaggerated variation in arterial pressure (>10-12 mm Hg) during quiet breathing (see Fig. 36.32B).[128,129] *Pulsus paradoxus* is not truly paradoxical, but rather an exaggeration of a normal variation in blood pressure that accompanies spontaneous ventilation. *Pulsus paradoxus* is a common and important sign in cardiac tamponade but may also be seen with pericardial constriction, severe airway obstruction, bronchospasm, dyspnea, or any condition that involves large swings in intrathoracic pressure. Importantly, though, in cases of cardiac tamponade, the *pulse pressure* and *left ventricular stroke volume* decrease during inspiration, in contrast to the pattern observed associated with large variations in intrathoracic pressure in which *pulse pressure* remains constant.[130]

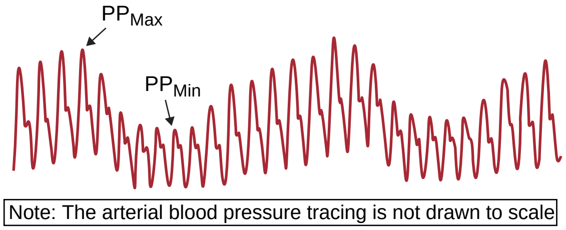
Arterial Pressure Monitoring and Waveform Analysis for Prediction of Volume Responsiveness

The starting point for volume resuscitation begins with optimizing cardiac preload, or more precisely, identifying the presence of residual preload reserve. The limitations and potential confounders of static indicators of preload such as central venous pressure (CVP) are well documented.[131] A wide array of dynamic markers of preload reserve and volume responsiveness have been described and evaluated for their ability to discriminate patients for whom volume expansion would be beneficial from those for whom it would not. These are largely based on cyclic variations in arterial blood pressure resulting from respiratory-induced changes in intrathoracic pressure.

During the inspiratory phase of a positive pressure breath, the increase in intrathoracic pressure simultaneously decreases LV afterload while increasing total lung volume which displaces blood from the pulmonary venous reservoir forward into the left side of the heart and increases LV preload. The increase in LV preload and decrease in afterload produce an increase in LV stroke volume, an increase in cardiac output, and in the absence of changes in system resistance, an increase in systemic arterial pressure. In most patients the preload effects predominate, but in patients with severe LV systolic failure, the reduction in afterload facilitates ventricular ejection. At the same time, rising intrathoracic pressure impairs systemic venous return and RV preload, possibly increasing RV afterload by slightly increasing pulmonary vascular resistance. These effects combine to reduce RV ejection during the early phase of inspiration. During the expiratory phase, however, the situation is reversed. The smaller stroke volume ejected from the RV during inspiration traverses the pulmonary vascular bed and enters the left heart, resulting in reduced LV filling, reduced LV stroke volume, and a fall in systemic arterial blood pressure. This cycle of increasing and decreasing stroke volume and systemic arterial blood pressure in response to inspiration and expiration is known as the *systolic pressure variation* (SPV).

SPV is often subdivided into inspiratory and expiratory components by measuring the increase (Δ Up) and decrease (Δ Down) in systolic pressure relative to the end-expiratory, apneic baseline pressure (Fig. 36.33). In a mechanically ventilated patient, normal SPV is 7 to 10 mm Hg, with Δ Up being 2 to 4 mm Hg and Δ Down being 5 to 6 mm Hg. Values greater than this are felt to indicate hypovolemia.[66,67] Both in experimental animals and critically ill patients, hypovolemia causes a dramatic increase in SPV, particularly the Δ Down component. Patients who manifest increased SPV during positive pressure mechanical ventilation may be described clinically as having residual preload reserve or being "volume responsive." While not synonymous with hypovolemia, preload reserve describes a physiologic state in which volume expansion or fluid challenge shifts the patient upward on the Frank-Starling curve resulting in increased stroke volume and increased cardiac output as long as systemic vascular resistance remains unchanged. Indeed, in a heterogeneous group of intensive care patients, Marik demonstrated that a large SPV (>15 mm Hg) was highly predictive of a low pulmonary artery wedge pressure (PAWP; <10 mm Hg), a surrogate for LV preload reserve.[132]

Pulse pressure variation (PPV), another dynamic indicator of preload reserve, is now available as part of standard monitoring software packages whenever an invasive arterial catheter is in use. In general, normal PPV is less than 13% to 17% (Fig. 36.34).[133-137] More sophisticated methods of pulse contour analysis allow real-time measurement of *stroke volume variation* (SVV), as well as calculation of a *stroke volume variation index*. When these measures exceed 10% to 13%, the patient is likely to have a positive response to volume expansion.[136,138] Although all of these dynamic measures are thought to indicate preload reserve, they are not interchangeable. PPV has been shown to diverge from SVV in the setting of vasopressor use or when the autonomic nervous system intervenes to preserve perfusion pressure in the face of falling stroke volume. In such cases, PPV will remain low while SVV increases.[139,140]



$PP_{Max} = 150–70 = 80$

$PP_{Min} = 120–60 = 60$

$PPV = (PP_{Max}–PP_{Min})/([PP_{Max}+PP_{Min}]/2)$

$PPV = 80–60/([80+60]/2) = 29\%$

Fig. 36.34 Pulse pressure variation. Pulse pressure variation *(PPV)* is calculated as the difference between maximal *(PP_{Max})* and minimal *(PP_{Min})* pulse pressure values during a single mechanical respiratory cycle, divided by the average of these two values. (Note that the arterial blood pressure trace is drawn for illustrative purposes and not to scale.)

Devices based on respiratory cycle-induced variation in the pulse plethysmogram have been developed as a similar but less invasive alternative for assessing preload reserve or volume responsiveness. Measures such as *photoplethysmography variation* (ΔPOP) or the *plethysmography variability index* appear to be useful when clinical and environmental conditions are optimal, but the transcutaneous oximetry signal is even more subject to confounding influences than the arterial blood pressure waveform.[135,141,142] Tidal volume, core and peripheral temperature, ambient light, and cardiac dysrhythmias pose significant impediments to valid and reproducible data collection and interpretation. There is no consensus regarding meaningful threshold values, and validity seems especially poor in children, in settings where patients are ventilated and sedated but not paralyzed, or in the setting of an open abdomen.[142] Furthermore, there are sophisticated auto-gaining features incorporated in most commercially available monitoring systems to optimize signal display. As such, the degree of variation visible to the naked eye may not correlate with true signal variation, resulting in erroneous clinical decisions and incorrect therapy.

Evidence is accumulating that dynamic measures are significantly superior to static indices of intravascular volume, especially in critically ill patients. Both PVV and SVV have been shown to be accurate following cardiac surgery in patients with normal and reduced ventricular function, while PPV was validated in assessing fluid responsiveness in patients with septic shock.[143,144] Intraoperative use has also been examined with similar results.[145,146] Indeed, the ability of clinicians to "eyeball" respiratory variation in the arterial blood pressure waveform as displayed on the monitor seems reasonably accurate. Subjective estimates of such pressure variation were incorrect only 4.4% of the time, a rate that would have resulted in only 1% of treatments being erroneous.[137]

There is disagreement on precise threshold values that differentiate fluid responders from non-responders, and the variety of techniques, devices, and approaches have not been standardized.[135] In a recent systematic review, mean discriminatory thresholds defining volume responsiveness for PVV and SVV were found to be 12.5% ± 1.6% and 11.6% ± 1.9%, respectively, with acceptable sensitivities and specificities (89%, 88% and 82%, 86%, respectively).[147] However, simply differentiating patients who will respond from those who will not fails to take into account the nature of the clinical intervention at issue. Volume expansion does not result in a dichotomous outcome, and the asymmetric nature of the Frank-Starling curve dictates that the cost-benefit ratio of acting in one direction will be different from acting in the other. For any given change in preload, the change in stroke volume will be different depending on the direction of the preload change, with that differential being dependent on how close to the peak of the curve the patient begins. Consequently, the concept of the "gray zone" has been proposed that defines a range of values between which evidence-based decision making is not possible.[148] For PPV, this zone has been described as 9% to 13% such that those above 13% should receive volume expansion while those below 9% should not. Between those two values, the measurement is not able to provide meaningful guidance and the decision should be based on other criteria.[136,149]

Continuous display of PPV is now routine on bedside monitors, a feature that has facilitated rapid adoption of dynamic preload reserve assessment.[150,151] As such, while its use is clinically relevant, it is even more important to understand the shortcomings of all respiratory-induced dynamic indicators and the clinical conditions under which they were originally studied and validated. While PPV appears to be valid in the setting of liver failure, it is significantly affected by increased abdominal pressure; patient position, including steep Trendelenburg, prone, or lateral positions; and use of vasopressors.[136,140,152-154] Variability in diastolic filling causing variable stroke volumes makes irregular heart rhythms highly problematic in the use of all dynamic preload reserve indicators.[155,156] In addition, there is evidence that patients with pulmonary hypertension or reduced RV ejection fraction may not have reliable responses to changes in intrathoracic pressure, increasing the risk of over-hydration and worsening right heart failure.[157] Dynamic indices are of marginal value in the setting of either minimally invasive or open thoracic surgery, and their use in children is considered unreliable due to the increased compliance of the myocardium and the chest wall in younger patients.[158,159] It has even been suggested that tachypnea, (especially in the setting of respiratory failure), or significant bradycardia may disrupt the relationship between respiratory-cycle–induced changes in intrathoracic pressure and cardiac chamber volumes, thus invalidating the theoretical basis for blood pressure variation analysis.[136]

Most importantly, though, is the profound effect of protective lung ventilation on the predictive power of respiratory-induced SPV, PPV, or SVV to identify a patient with residual preload reserve.[160-162] Mechanical ventilation with tidal volume of 8 to 10 mL/kg, positive end-expiratory pressure ≥ 5 mm Hg, regular cardiac rhythm, normal intra-abdominal pressure, and a closed chest are necessary to duplicate the experimental conditions under which most of these indices have been investigated, and these conditions are largely inconsistent with ventilatory parameters chosen for lung protective ventilation. Clinical trials have found waveform analysis to be of limited utility in this setting.[160-162] However, measuring PPV or SVV during or immediately following a recruitment maneuver increased its sensitivity and specificity in predicting fluid responsiveness, although a broader gray zone of up to 26% should be considered.[163,164]

As noted above, respiratory-cycle–induced arterial pressure variations are dependent on changes in LV preload and, to a lesser degree, afterload. Indeed, decreased arterial compliance and the resultant increased pulse pressure that accompanies both normal and pathologic vascular aging results in an exaggerated PPV response to any change in stroke volume. As such, it is possible that PPV thresholds should be higher in such patients than in those with greater elastance in their vascular trees.[165,166]

Central Venous Pressure Monitoring

Cannulation of a central vein and direct measurement of CVP are frequently performed in hemodynamically unstable patients and those undergoing major operations. A central venous catheter may be inserted to provide secure vascular access for administration of vasoactive drugs or fluids, CVP monitoring, transvenous cardiac pacing, temporary hemodialysis, pulmonary artery catheterization (PAC) for more comprehensive cardiac monitoring, or aspiration of entrained air in patients at risk for venous air emboli. A central venous catheter may also be inserted when no peripheral access can be obtained, or when repeated venous blood sampling is required (Box 36.5).

BOX 36.5 **Indications for Central Venous Cannulation**

- Central venous pressure monitoring
- Pulmonary artery catheterization and monitoring
- Transvenous cardiac pacing
- Temporary hemodialysis
- Drug administration
  - Concentrated vasoactive drugs
  - Hyperalimentation
  - Chemotherapy
  - Agents irritating to peripheral veins
  - Prolonged antibiotic therapy (e.g., endocarditis)
- Rapid infusion of fluids (via large cannulas)
  - Trauma
  - Major surgery
- Aspiration of air emboli
- Inadequate peripheral intravenous access
- Sampling site for repeated blood testing

CENTRAL VENOUS CANNULATION

When required in the intraoperative period, the decision to perform central venous cannulation before or after induction of anesthesia is guided most often by individual patient and physician preferences or institutional practice.

CHOOSING THE CATHETER, SITE, AND METHOD FOR CENTRAL VENOUS CANNULATION

Central venous catheters come in a variety of lengths, gauges, compositions, and lumen numbers.[167,168] This makes it critical for the physician to choose the best catheter for any given application. Multiport catheters, which allow monitoring of CVP and infusion of drugs and fluids simultaneously, are the most common,[169] but introducer sheaths with one or two integrated ports for multiple drug infusions are an alternative. Introducer sheaths allow insertion of a single-lumen catheter through the hemostasis valve for continuous CVP monitoring and rapid placement of a pacing wire or PAC for more intensive monitoring should the need arise.

Selecting the best site for safe and effective central venous cannulation ultimately requires consideration of the indication for catheterization (pressure monitoring versus drug or fluid administration), the patient's underlying medical condition, the clinical setting, and the skill and experience of the physician performing the procedure. In patients with severe bleeding diatheses, it is best to choose a puncture site where bleeding from the vein or adjacent artery is easily detected and controlled with local compression. In such a patient, an internal or external jugular approach would be preferable to a subclavian site. Likewise, patients with severe emphysema or others who would be severely compromised by a pneumothorax would be better candidates for internal jugular than subclavian cannulation, owing to the higher risk with the latter approach. If transvenous cardiac pacing is required in an emergency situation, catheterization of the right internal jugular vein is recommended, as it provides the most direct route to the right ventricle. Trauma patients, with their necks immobilized in a hard cervical collar, are best resuscitated using a femoral or subclavian approach; the latter may be placed even more safely if the risk of pneumothorax is obviated by prior placement of a thoracostomy tube. The physician must recognize that the length of catheter inserted to position the catheter tip properly in the superior vena cava will vary according to puncture site, being slightly (3-5 cm) greater when the left internal or external jugular veins are chosen, compared with the right internal jugular vein.[170] Finally, a physician's personal experience undoubtedly plays a significant role in determining the safest site for central venous cannulation, particularly when the procedure is performed under urgent or emergent circumstances.

A central vein may be cannulated using either a landmark technique or ultrasound guidance. Ultrasound technology is now widely available and is strongly recommended for central line placement.[171-173] The reader is referred to other sources for detailed descriptions and tutorials on the various insertion techniques for different access sites.[169,174-176] Regardless of the insertion technique used or the cannulation site chosen, certain general principles should be emphasized. Ideally, a protocol or checklist describing the basic procedural steps for central line insertion should be in place at every institution, and all staff members should feel empowered to speak up when they witness a protocol violation. Standardized equipment, routine use of an assistant, hand washing, and maximal barrier precautions all contribute to the sterility of the procedure.[172] The use of real-time ultrasound guidance for vessel localization and venipuncture should be routine or at least strongly considered, especially when the internal jugular vein site is selected. Waveform manometry or pressure measurement

BOX 36.6 Complications of Central Venous Pressure Monitoring

- Mechanical
  - Vascular injury
    - Arterial
    - Venous
    - Cardiac tamponade
  - Respiratory compromise
    - Airway compression from hematoma
    - Pneumothorax
  - Nerve injury
  - Arrhythmias
- Thromboembolic
  - Venous thrombosis
  - Pulmonary embolism
  - Arterial thrombosis and embolism
  - Catheter or guidewire embolism
- Infectious
  - Insertion site infection
  - Catheter infection
  - Bloodstream infection
  - Endocarditis
- Misinterpretation of data
- Misuse of equipment

should be used to confirm venous placement of the catheter before use. Finally, the position of the catheter tip should be verified as soon as clinically appropriate to avoid delayed complications.

COMPLICATIONS OF CENTRAL VENOUS PRESSURE MONITORING

Complications of central venous cannulation are becoming increasingly recognized as major sources of morbidity with more than 15% of patients experiencing some sort of related adverse event.[177,178] Although serious immediate complications are infrequent when these procedures are performed by well-trained, experienced clinicians, use of CVP catheters continues to result in significant morbidity and mortality. Complications are often divided into mechanical, thromboembolic, and infectious etiologies (Box 36.6).

Mechanical Complications of Central Venous Catheterization

The incidence of complications depends on a number of factors including the catheter insertion site and the patient's medical condition. Large retrospective and observational studies provide the best estimates of incidence and frequency.

Vascular injuries from central venous catheterization have a range of clinical consequences. The most common minor complications are localized hematoma or injury to the venous valves.[179] More serious complications include perforation into the pleural space or mediastinum, resulting in hydrothorax, hemothorax, hydromediastinum, hemomediastinum, and or chylothorax.[180-186]

In general, *unintended arterial puncture* is the most common acute mechanical complication, ranging from 1.9 to 15%.[187] Many of these injuries result in localized hematoma formation, but in rare occasions even small-gauge-needle punctures may lead to serious complications such as arterial thromboembolism.[188] Delayed vascular complications following central venous catheterization are uncommon but should be considered as consequences of this procedure. A number of these have been described in the literature, including aorto-atrial fistula, venobronchial fistula, carotid artery–internal jugular vein fistula, and pseudoaneurysm formation.[189-192]

The most important life-threatening vascular complication of central venous catheterization is **cardiac tamponade** resulting from perforation of the intrapericardial superior vena cava, right atrium, or right ventricle, and resulting hemopericardium or unintentional pericardial instillation of intravenous fluid.[193] Most reports document the avoidable nature of this catastrophic event and highlight that patients are predisposed to this complication when central venous catheter tips are malpositioned within the heart chambers or abutting the wall of the superior vena cava at a steep angle. This latter position can be recognized radiographically as a gentle curvature of the catheter tip within the superior vena cava.[194] These observations emphasize that objective confirmation of proper catheter tip location is mandatory, regardless of whether the catheter is inserted from a central or peripheral site.

Pneumothorax is often cited as the most common complication of subclavian vein cannulation, although it appears that unintended arterial puncture is actually more frequent.[99,195] Mansfield et al. reported 821 patients who underwent attempted subclavian venous cannulation, with a 1.5% incidence of pneumothorax and a 3.7% incidence of arterial puncture when using the landmark technique.[195] Pneumothorax is even less frequent with the internal jugular approach. Shah et al. reported an incidence of pneumothorax of 0.5% in their series of nearly 6000 internal jugular catheterizations.[187] This is most likely a high estimate, as these patients had undergone sternotomy for cardiac surgery, a procedure that may have been responsible for the pneumothorax in many cases.

Nerve injury is another potential complication of central venous cannulation. Damage may occur to the brachial plexus, stellate ganglion, phrenic nerve, or vocal cords.[196-198] In addition, chronic pain syndromes have been attributed to this procedure.[199]

Thromboembolic Complications of Central Venous Catheterization

Catheter-related thrombosis varies according to the site of central venous catheterization, occurring in as many as 21.5% of patients with femoral venous catheters and 1.9% of those with subclavian venous catheters.[200] Catheters that are positioned low in the right atrium may be more prone to thrombus formation, possibly due to mechanical irritation of the right atrial endocardium by the catheter.[201] Thrombi that form at the catheter tip or adhere to the endocardium have the potential to become a nidus for infection, cause superior vena cava syndrome, or embolize into the pulmonary circulation.[202-204] Occasionally, surgical removal is required.[205]

In addition to thromboembolism, other reported embolic complications of central venous catheterization include embolism of portions of the catheter or guidewire, and air embolism.[206,207] Almost invariably, these are the result of misuse of equipment, highlighting the need for proper education and training of nurses and physicians responsible for the use of these devices.

Infectious Complications of Central Venous Catheterization

By far, the most common major late complication of central venous cannulation is *infection.* Major progress has been made in the control of central line-associated blood stream infections (CLABSI), likely due to a focus on evidence-based best practices for catheter insertion and maintenance.[208] In fact, CLABSI rates have declined by about 50% between 2008 and 2016.[209] The majority of CLABSIs are occurring in inpatient wards and outpatients receiving hemodialysis, but approximately one third of these cases still occur in the ICU, a cohort that likely includes most of the catheters placed intraoperatively.[209-211]

As previously noted, the starting point for prevention of infection is meticulous attention to aseptic technique.[212] Multilumen catheters may carry a higher risk of infection than single-lumen catheters although the added clinical functionality of such catheters often mandates their use.[178,213] Catheters are made from materials such as silicone, polyvinyl chloride, Teflon, and polyurethane. Furthermore, catheters of the same material may be manufactured differently, which influences their surfaces and the frequency of bacterial adherence to the surface.[214] Heparin-bonded central venous catheters have been shown to reduce the incidence of catheter-related thrombosis and infection in children and adults.[215,216] The incorporation of antimicrobial treatments such as silver (this metal has broad antimicrobial activity and is nontoxic), combinations of the antiseptics chlorhexidine and silver sulfadiazine, or the antibiotics minocycline and rifampin onto the catheter surfaces have been shown to reduce rates of catheter colonization and in some cases blood stream infection.[216-218] The added expense has prevented more widespread adoption of these catheters, although an analysis has suggested their cost-effectiveness in settings in which the rate of catheter-related infections remains high (more than 3.3 per 1000 catheter days).[219]

A chlorhexidine gluconate-impregnated sponge dressing has been shown to reduce catheter colonization in infants and children, but does not reduce the rate of catheter-associated bloodstream infections.[220,221] Current guidelines from the Centers for Disease Control and Prevention do not support routine catheter site changes or scheduled changes over a guidewire and provide other detailed recommendations for catheter management to reduce the risk of infectious complications.[213,222]

Overall, there does not appear to be an ideal site for central venous cannulation with respect to prevention of complications given that, taken together, the risk of mechanical, thrombotic, and infectious complications is similar among the three insertion sites. This was illustrated by a recent prospective, randomized, multicenter trial in adult ICU patients, where catheterization of the subclavian vein is associated with the lowest risk of infectious complications and deep vein thrombosis, but the highest risk of mechanical complications.[223]

TABLE 36.2 Normal Cardiovascular Pressures

Pressures	Average (mm Hg)	Range (mm Hg)
RIGHT ATRIUM		
a wave	6	2-7
v wave	5	2-7
Mean	3	1-5
RIGHT VENTRICLE		
Peak systolic	25	15-30
End-diastolic	6	1-7
PULMONARY ARTERY		
Peak systolic	25	15-30
End-diastolic	9	4-12
Mean	15	9-19
PULMONARY ARTERY WEDGE		
Mean	9	4-12
LEFT ATRIUM		
a wave	10	4-16
v wave	12	6-21
Mean	8	2-12
LEFT VENTRICLE		
Peak systolic	130	90-140
End-diastolic	8	5-12
Central aorta		
Peak systolic	130	90-140
End-diastolic	70	60-90
Mean	90	70-105

Other Complications of Central Venous Catheterization

Although many complications of CVP monitoring relate to equipment misuse, the frequency of complications caused by data misinterpretation remains unknown. It is extremely likely, however, that clinicians misinterpret CVP measurements and have suboptimal understanding of CVP monitoring, just as has been demonstrated repeatedly for PAC monitoring (see discussion later). Safe and effective use of CVP monitoring requires a detailed understanding of cardiovascular physiology, normal CVP waveforms, and common pathologic abnormalities in these measurements.

PHYSIOLOGIC CONSIDERATIONS FOR CENTRAL VENOUS PRESSURE MONITORING

Cardiac filling pressures are measured directly from a number of sites in the vascular system. CVP monitoring is the least invasive method, followed by pulmonary artery and left atrial pressure monitoring. Proper interpretation of all cardiac filling pressures requires knowledge of normal values for these pressures, as well as pressures in the cardiac chambers, the great vessels, and other measured and derived hemodynamic variables (Table 36.2).

Two prerequisites must be met in order to correctly interpret the information provided by the CVP monitor: (a) the clinician must possess a thorough understanding of all the variables that affect right atrial pressure; and (b) measurements need to be made with extreme attention to detail.

CVP is determined by the interaction of the venous return function of the circulatory system and the cardiac function.[224] An increase in cardiac function with an increase in venous return will result in an increase in cardiac output and *rise* in CVP. An increase in cardiac function *without* an increase in venous return will result in an increase in cardiac output and a *fall* in CVP. In other words, an isolated CVP measurement has very little meaning unless the information is interpreted in the context of some estimation of cardiac function.

Central Venous Pressure and Venous Return

What determines venous return to the heart? The relationship among the multiple variables that affect blood return to the right atrium is complex. In short, venous return is mostly determined by the gradient between the *mean circulatory filling pressure* (MCFP) and CVP.[131] MCFP results from the elastic recoil pressure from distended small veins and venules and is the force that drives blood back to the right atrium.[224] This pressure has been estimated to be between 8 and 10 mm Hg in healthy individuals at rest, but it cannot be measured in the clinical setting.[225] MCFP rises when volume is administered intravenously, but also in many other circumstances such as when venous tone changes in response to venoconstrictors or endogenous catecholamines, or when there is a shift of blood volume from the splanchnic system into the systemic circulation.[131] The CVP, typically 2 to 3 mm Hg in healthy individuals, is the downstream pressure. Two important corollaries emerge: right atrial pressure is key for maintaining cardiac output, and the body will compensate through the mechanisms described above and others to preserve venous return. This explains why a patient may lose 10% to 12% of his circulating blood volume without exhibiting changes in blood pressure or CVP. Secondly, the difference between MCFP and CVP is only 6 to 8 mm Hg, and hence small changes in CVP may have profound hemodynamic consequences.

Central Venous Pressure and Cardiac Function

The exact same amount of blood returning to the heart can result in very different CVP values at different cardiac function states. This may be explained by the classic diastolic pressure-volume relationship. This curve is one limb of a pressure-volume loop that describes the relation between pressure and volume for the left or right ventricle during an entire cardiac cycle. When a ventricle is operating along the flat portion of its diastolic filling curve it will exhibit only a small increase in filling pressure (CVP in the case of the right ventricle) after significant increases in filling volume or preload. The same increase in filling volume causes a significant increase in filling pressure when the ventricle is operating on the steep portion of its curve.[226] An even more confusing situation arises when the diastolic pressure-volume relation of the ventricle changes, for example with the onset of myocardial ischemia. Rather than moving along the same diastolic pressure-volume curve, the ventricle now shifts to a different, steeper curve where, somewhat paradoxically, an increase in filling pressure may accompany a decrease in filling volume.[227] As in this example, not only can one not assume that a given measured change in cardiac filling pressure reflects a proportional change in ventricular preload, it cannot even be assumed that pressure and volume change in the same direction.[227] In summary, changes in CVP may be the sole result of changes in inotropic state or compliance of the ventricle, independent of the total circulating volume or venous return to the heart.

To summarize, CVP is the result of a complex and diverse interplay among many different physiologic variables, many of which are impossible to measure in the operating room or ICU. It is therefore not surprising that studies assessing the value of CVP as a predictor of volume status or fluid responsiveness have failed to demonstrate a relationship. There is, in fact, no simple relationship between CVP and circulating blood volume.[131]

Further complicating the analysis are the effects of intrathoracic and intrapericardial pressures on filling pressures such as CVP.[226,228] In general, all intravascular pressures measured in clinical practice are referenced to ambient atmospheric pressure. Thus, a cardiac filling pressure of 10 mm Hg is 10 mm Hg higher than ambient atmospheric pressure. Does this pressure value accurately represent the distending force across the cardiac chamber wall at end-diastole?

To answer this question, one needs to consider transmural pressure. The cardiac chambers are all contained within the pericardium and thorax. Changes in pressure in the structures surrounding the heart will influence pressures recorded within the heart. Transmural pressure is the difference between chamber pressure and juxtacardiac or pericardial pressure. This transmural pressure determines ventricular preload, end-diastolic volume, or fiber length. The same measured filling pressure, referenced to atmospheric pressure, can be associated with markedly different transmural pressures and chamber volumes, depending on whether juxtacardiac pressure is high or low. Although juxtacardiac pressure can be ignored under some circumstances, marked alterations in pleural and pericardial pressures occur commonly and must be considered when any cardiac filling pressure is interpreted. Transmural pressure is always the pressure of physiologic interest. Because juxtacardiac pressure is not measured routinely, one must always consider that the measured central vascular pressure, referenced to the ambient atmosphere, may be a poor estimate of transmural pressure.[226,228]

During spontaneous breathing, inspiration causes a decrease in pleural and juxtacardiac pressures which is transmitted, in part, to the right atrium, and lowers CVP. This same decrease in pleural pressure will influence other measured central vascular pressures in a similar fashion. Note a subtle but critically important observation about the measurement of central vascular pressures. Although CVP measured relative to atmospheric pressure decreases during the inspiratory phase of spontaneous ventilation, transmural CVP, the difference between right atrial pressure and juxtacardiac pressure may actually increase slightly as more blood is drawn into the right atrium. The opposite pattern is observed during positive-pressure ventilation, in which inspiration increases intrathoracic pressure while raising the measured CVP, but decreases transmural CVP,

TABLE 36.3 Central Venous Pressure Waveform Components

Waveform Component	Phase of Cardiac Cycle	Mechanical Event
a wave	End-diastole	Atrial contraction
c wave	Early systole	Isovolumic ventricular contraction, tricuspid motion toward right atrium
v wave	Late systole	Systolic filling of atrium
h wave	Mid- to late diastole	Diastolic plateau
x descent	Mid-systole	Atrial relaxation, descent of the base, systolic collapse
y descent	Early diastole	Early ventricular filling, diastolic collapse

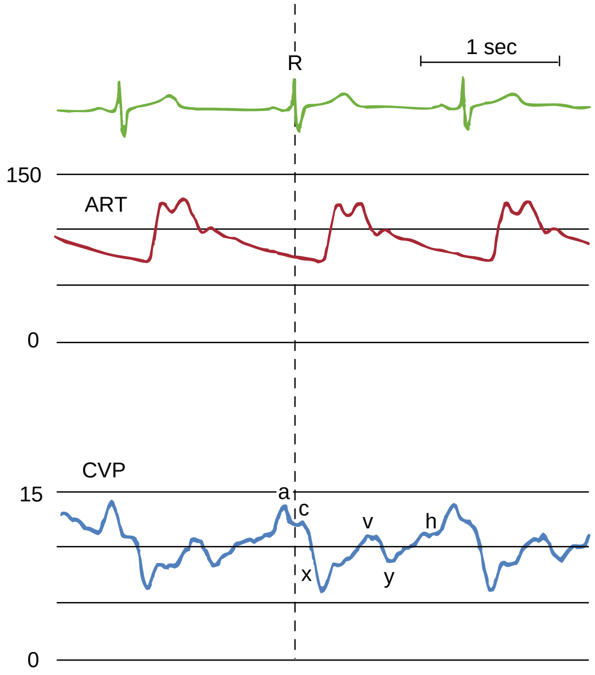


Fig. 36.35 Normal central venous pressure *(CVP)* waveform. The diastolic components (y descent, end-diastolic a wave) and the systolic components (c wave, x descent, end-systolic v wave) are all clearly delineated. A mid-diastolic plateau wave, the h wave, is also seen because heart rate is slow. Waveform identification is aided by timing the relation between individual waveform components and the electrocardiographic R wave. Waveform timing using the arterial *(ART)* pressure trace is more confusing, owing to the relative delay in the systolic arterial pressure upstroke. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

because the elevated intrathoracic pressure reduces venous return. As mentioned before, transmural pressures are rarely measured in clinical practice owing to difficulties in assessing juxtacardiac or intrathoracic pressure. Instead, end-expiratory values for cardiac filling pressures should be recorded in all patients, to provide the best estimate of transmural pressure. At the end of expiration, intrathoracic and juxtacardiac pressures approach atmospheric pressure regardless of ventilatory status and the CVP values will coincide. Proper pressure values can also be determined by visual inspection of the CVP waveform on a calibrated monitor screen or paper recording. This facilitates comparison of CVP values (and other cardiac filling pressures) obtained from the same patient under varying patterns of ventilation, a common situation in anesthesia and critical care.

The second prerequisite for interpretation of CVP values is correct measurement. Details about the correct zeroing and leveling of the transducer are discussed elsewhere in this text. (See Technical Aspects of Direct Blood Pressure Measurement.). Leveling of the transducer for accurate CVP measurements is best achieved by aligning the stopcock (not the transducer) to a point 5 cm below the sternal angle, as opposed to the more commonly used mid-axillary line at the fourth intercostal space. When this reference point is used, measurements can be done in both the supine position or with the patient sitting up (up to an angle of 60 degrees),[116,229,230] and better represent the upper fluid level of the right atrium. Regardless of the position chosen, it is most important to be consistent throughout the monitoring period to maintain the same reference point.

Despite these limitations, there is still a great deal of information that may be gathered from careful interpretation of the CVP waveform. For this, it is essential to understand the components of the normal CVP waveform.

NORMAL CENTRAL VENOUS PRESSURE WAVEFORMS

Mechanical events during the cardiac cycle are responsible for the sequence of waves seen in a typical CVP trace. The CVP waveform consists of five phasic events, three peaks (a, c, v) and two descents (x, y) (Table 36.3, Fig. 36.35).[231,232] The most prominent wave is the **a wave** of atrial contraction, which occurs at end-diastole following the ECG P wave. Atrial contraction increases atrial pressure and provides the “atrial kick” to fill the right ventricle through the open tricuspid valve. Atrial pressure decreases following the a wave, as the atrium relaxes. This smooth decline in pressure is interrupted by the **c wave**. This wave is a transient increase in atrial pressure produced by isovolumic ventricular contraction, which closes the tricuspid valve and displaces it toward the atrium. The c wave always follows the ECG R wave because it is generated during onset of ventricular systole. (Note that the c wave observed in a jugular venous pressure trace might have a slightly more complex origin. This wave has been attributed to early systolic pressure transmission from the adjacent carotid artery and may be termed a carotid impact wave.[233] Because the jugular venous pressure also reflects right atrial pressure, however, this c wave likely represents both arterial [carotid impact] and venous [tricuspid motion] origins.) Atrial pressure continues its decline during ventricular systole, owing to continued atrial relaxation and changes in atrial geometry produced by ventricular contraction and ejection that draw the tricuspid annulus toward the cardiac apex. This is the **x descent** or systolic collapse in atrial pressure. The x descent can be divided into two portions, x and x′, corresponding to the segments before and after the c wave. The last atrial pressure peak is the **v wave**, and is caused by venous filling of the atrium during late systole while the tricuspid valve remains closed. The v wave usually peaks just after the ECG T wave. Atrial pressure then decreases, inscribing the **y descent** or diastolic collapse, as the tricuspid valve opens and blood flows from atrium to ventricle. (A final component of the CVP waveform, the **h wave**, occasionally appears as a pressure plateau in mid- to late diastole. The h wave is not normally seen unless the heart rate is slow and venous pressure is elevated.)[233,234] In summary, the normal venous waveform components may be remembered as follows: the a wave results from atrial contraction; the c wave from tricuspid valve closure and isovolumic RV contraction; the x descent is the systolic decrease in atrial pressure due to atrial relaxation and ventricular contraction; the v wave from ventricular ejection, which drives venous filling of the atrium; and the y descent is the diastolic decrease in atrial pressure due to flow across the open tricuspid valve.

In relation to the cardiac cycle and ventricular mechanical actions, the CVP waveform can be considered to have three systolic components (c wave, x descent, v wave) and two diastolic components (y descent, a wave). By recalling the mechanical actions that generate the pressure peaks and troughs, it is easy to identify these waveform components properly by aligning the CVP waveform and the ECG trace and using the ECG R wave to mark end-diastole and onset of systole. When the radial artery pressure trace is used for CVP waveform timing instead of the ECG, confusion may arise because the arterial pressure upstroke occurs nearly 200 ms after the ECG R wave (see Fig. 36.35). This normal physiologic delay reflects the times required for the spread of the electrical depolarization through the ventricle (≈60 ms), isovolumic LV contraction (≈60 ms), transmission of aortic pressure rise to the radial artery (≈50 ms), and transmission of the radial artery pressure rise through fluid-filled tubing to the transducer (≈10 ms).[117,235]

The normal CVP peaks are designated systolic (c, v) or diastolic (a) according to the phase of the cardiac cycle in which the wave begins. However, one generally identifies these waves not by their onset or upstroke, but rather by the location of their peaks. For instance, the a wave generally begins and peaks in end-diastole, but the peak may appear delayed to coincide with the ECG R wave, especially in a patient with a short PR interval. In this instance, a and c waves merge, and this composite wave is termed an a-c-wave. Designation of the CVP v wave as a systolic event may be even more confusing. Although the ascent of the v wave begins during late systole, the peak of the v wave occurs during isovolumic ventricular relaxation, immediately prior to atrioventricular valve opening and the y descent. Consequently, the most precise description would be that the v wave begins in late systole, but peaks during isovolumic ventricular relaxation, the earliest portion of diastole. For clinical purposes, it is simplest to consider the v wave to be a systolic wave.

Although three distinct CVP peaks (a, c, v) and two troughs (x, y) are discernible in the normal venous pressure trace, heart rate changes and conduction abnormalities alter this pattern. A short ECG PR interval causes fusion of a and c waves, and tachycardia reduces the length of diastole and the duration of the y descent, causing v and a waves to merge. In contrast, bradycardia causes each wave to become more distinct with separate x and x' descents visible and a more prominent h wave. Although there are circumstances in which other pathologic waves may be evident in the CVP trace, one should resist the temptation to assign physiologic significance to each small pressure peak, as many will arise as artifacts of fluid-filled tubing-transducer monitoring systems. It is more useful to search for the expected waveform components, including those waveforms that are characteristic of the pathologic conditions suspected.

TABLE 36.4 Central Venous Pressure Waveform Abnormalities

Condition	Characteristics
Atrial fibrillation	Loss of a wave Prominent c wave
Atrioventricular dissociation	Cannon a wave
Tricuspid regurgitation	Tall systolic c-v-wave Loss of x descent
Tricuspid stenosis	Tall a wave Attenuation of y descent
Right ventricular ischemia	Tall a and v waves Steep x and y descents M or W configuration
Pericardial constriction	Tall a and v waves Steep x and y descents M or W configuration
Cardiac tamponade	Dominant x descent Attenuated y descent
Respiratory variation during spontaneous or positive-pressure ventilation	Measure pressures at end-expiration

ABNORMAL CENTRAL VENOUS PRESSURE WAVEFORMS

Various pathophysiologic conditions may be diagnosed or confirmed by examination of the CVP waveform (Table 36.4). One of the most common applications is the rapid diagnosis of cardiac arrhythmias.[236] In **atrial fibrillation** (Fig. 36.36A), the a wave disappears and the c wave becomes more prominent because atrial volume is greater at end-diastole and onset of systole, owing to the absence of effective atrial contraction. Occasionally, atrial fibrillation or flutter waves may be seen in the CVP trace when the ventricular rate is slow. Isorhythmic **atrioventricular dissociation or accelerated junctional (nodal) rhythm** (see Fig. 36.36B) alters the normal sequence of atrial contraction prior to ventricular contraction. Instead, atrial contraction now occurs during ventricular systole when the tricuspid valve is closed, thereby inscribing a tall "cannon" a wave in the CVP waveform. Absence of normal atrioventricular synchrony during ventricular pacing (see Fig. 36.36C) can be identified in a similar fashion by searching for cannon waves in the venous pressure trace. In these instances, the CVP helps diagnose the cause of arterial hypotension; loss of the normal end-diastolic atrial kick may not be as evident in the ECG trace as it is in the CVP waveform.

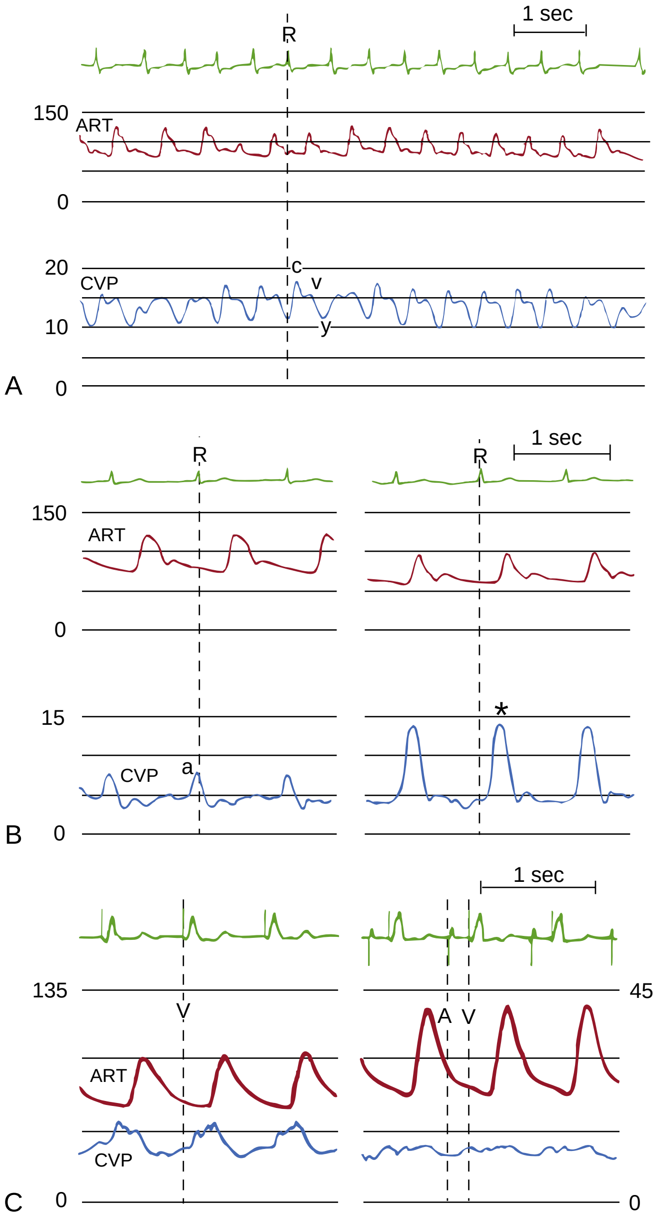

Fig. 36.36 Central venous pressure *(CVP)* changes caused by cardiac arrhythmias. (A) Atrial fibrillation. Note absence of the a wave, a prominent c wave, and a preserved v wave and y descent. This arrhythmia also causes variation in the electrocardiographic (ECG) R-R interval and left ventricular stroke volume, which can be seen in the ECG and arterial *(ART)* pressure traces. (B) Isorhythmic atrioventricular dissociation. In contrast to the normal end-diastolic a wave in the CVP trace *(left panel)*, an early systolic cannon wave is inscribed (*, *right panel*). Reduced ventricular filling accompanying this arrhythmia causes a decreased arterial blood pressure. (C) Ventricular pacing. Systolic cannon waves are evident in the CVP trace during ventricular pacing *(left panel)*. Atrioventricular sequential pacing restores the normal venous waveform and increases arterial blood pressure *(right panel)*. ART scale left, CVP scale right. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

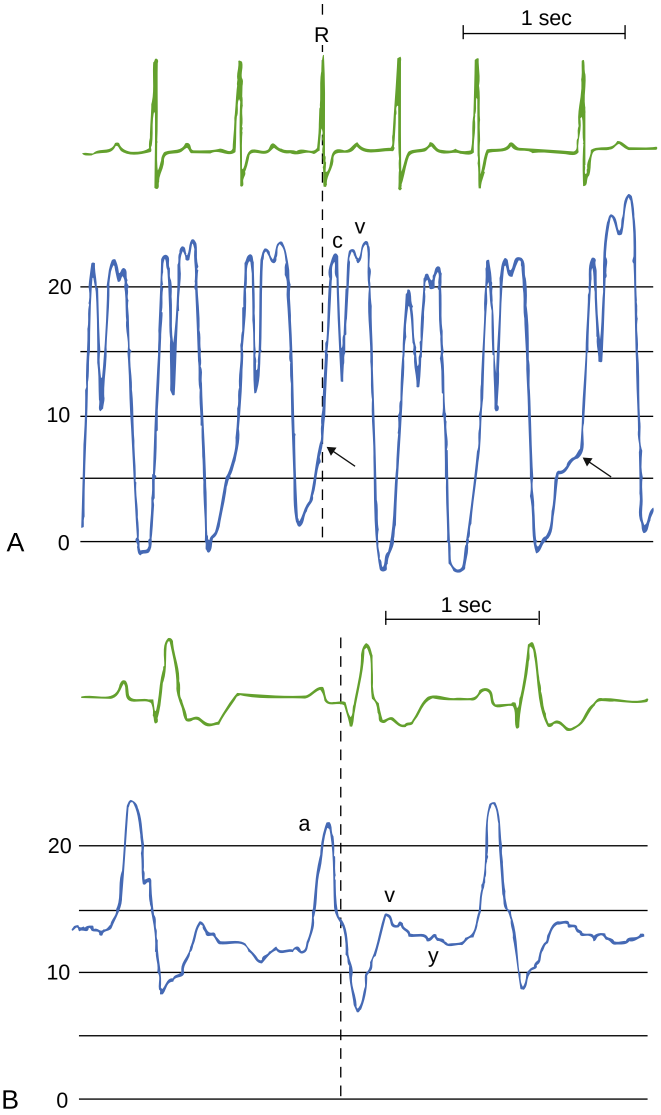

Fig. 36.37 Central venous pressure (CVP) changes in tricuspid valve disease. (A) Tricuspid regurgitation increases mean CVP, and the waveform displays a tall systolic c-v-wave that obliterates the x descent. In this example, the a wave is not seen because of atrial fibrillation. Right ventricular end-diastolic pressure is estimated best at the time of the electrocardiographic R wave *(arrows)* and is lower than mean CVP. (B) Tricuspid stenosis increases mean CVP, the diastolic y descent is attenuated, and the end-diastolic a wave is prominent. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

Right-sided valvular heart diseases alter the CVP waveform in different ways.[237] **Tricuspid regurgitation** (Fig. 36.37A) produces abnormal systolic filling of the right atrium through the incompetent valve. A broad, tall systolic c-v-wave results, beginning in early systole and obliterating the systolic x descent in atrial pressure. The CVP trace is said to be ventricularized, resembling RV pressure.

Note that this regurgitant wave differs in onset, duration, and magnitude from a normal v wave caused by end-systolic atrial filling from the venae cavae. In patients with tricuspid regurgitation, RV end-diastolic pressure is overestimated by the numeric display on the bedside monitor, which reports a single mean value for CVP. Instead, RV end-diastolic pressure is estimated best by measuring the CVP value at the time of the ECG R wave, prior to the regurgitant systolic wave (see Fig. 36.37A). Unlike tricuspid regurgitation, **tricuspid stenosis** produces a diastolic defect in atrial emptying and ventricular filling (see Fig. 36.37B). Mean CVP is elevated, and a pressure gradient exists throughout diastole between right atrium and ventricle. The a wave is unusually prominent and the

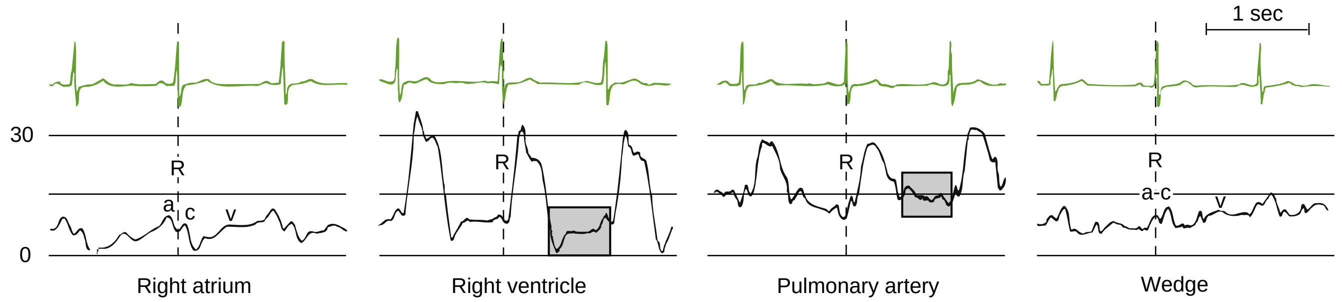

Fig. 36.38 Characteristic waveforms recorded during passage of the pulmonary artery catheter. The right atrial pressure resembles a central venous pressure waveform and displays a, c, and v waves. Right ventricular pressure shows a higher systolic pressure than seen in the right atrium, although the end-diastolic pressures are equal in these two chambers. Pulmonary artery pressure shows a diastolic step-up compared with ventricular pressure. Note also that right ventricular pressure increases during diastole, whereas pulmonary artery pressure decreases during diastole *(shaded boxes)*. Pulmonary artery wedge pressure has a similar morphology to right atrial pressure, although the a-c and v waves appear later in the cardiac cycle relative to the electrocardiogram. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

y descent is attenuated, owing to the impaired diastolic egress of blood from the atrium. Other conditions that reduce RV compliance, such as RV ischemia, pulmonary hypertension, or pulmonic valve stenosis, may produce a prominent end-diastolic a wave in the CVP trace but do not attenuate the early diastolic y descent. CVP waveform morphology changes in other characteristic ways in the presence of pericardial diseases and RV infarction. These patterns are interpreted best in conjunction with PAP monitoring, which is discussed below.

Perhaps the most important traditional application of CVP monitoring is to provide an estimate of the adequacy of the circulating blood volume. Several randomized trials and systematic reviews have demonstrated a very poor relationship between CVP and circulating blood volume, as well as the inability of a static CVP value to predict the hemodynamic response to a fluid challenge.[238-240] This is not surprising in light of the factors described above. Some have argued that the important clinical question with regard to volume responsiveness should be phrased in the negative, that is, whether a patient is *unlikely* to respond to fluids. The subset of patients that will derive all the deleterious effects of fluid administration (capillary leak and tissue edema) and no benefit (increased cardiac output) is in most instances the group of clinical interest. In this regard, the lack of an inspiratory fall in CVP in patients who have spontaneous inspiratory efforts (provided the inspiratory effort is adequate, i.e., >2 mm Hg fall in PAOP with inspiration) was able to predict no improvement in cardiac output following fluid administration.[241]

Pulmonary Artery Catheter Monitoring

In 1970, Swan, Ganz, and colleagues introduced PAC into clinical practice for the hemodynamic assessment of patients with acute myocardial infarction.[242] This device allowed accurate bedside measurement of important cardiovascular physiologic variables, and its popularity soared. While the PAC provides measurements of several hemodynamic variables that clinicians find it hard to predict accurately from standard clinical signs and symptoms,[243] it remains uncertain whether PAC monitoring leads to improved patient outcome.[244]

PULMONARY ARTERY CATHETER INSERTION

The standard PAC has a 7.0 to 9.0 Fr circumference, is 110 cm in length marked at 10-cm intervals, and contains four internal lumens. The distal port at the catheter tip is used for PAP monitoring, while the second is 30 cm more proximal and is used for CVP monitoring. The third lumen leads to a balloon near the tip which is used to float the catheter through the cardiac chambers, and the fourth houses wires for a temperature thermistor, the end of which lies just proximal to the balloon.[245]

PACs can be placed from any of the central venous cannulation sites described earlier, but the right internal jugular vein provides the most direct route to the right heart chambers. The balloon at the tip of the catheter is inflated with air, and the catheter is advanced into the right atrium, through the tricuspid valve, the right ventricle, the pulmonic valve, into the pulmonary artery, and finally into the wedge position. Characteristic waveforms from each of these locations confirm proper catheter passage and placement (Fig. 36.38).

After the PAWP is measured, the balloon is deflated, and the PAP waveform should reappear. Catheter position is confirmed with a chest radiograph. The tip of the PAC should be within 2 cm of the cardiac silhouette on a standard anteroposterior chest film.[246]

If an RV waveform is not observed after inserting the catheter 40 cm, coiling in the right atrium is likely. Similarly, if a pulmonary artery waveform is not observed after inserting the catheter to 50 cm, coiling in the right ventricle has probably occurred. The balloon should be deflated, the catheter withdrawn to 20 cm, and the PAC floating sequence repeated.

A few additional points might aid successful positioning of the PAC. The air-filled balloon tends to float to nondependent regions as it passes through the heart into the pulmonary vasculature. Consequently, positioning a patient head down will aid flotation across the tricuspid valve, and tilting the patient onto the right side and placing the head up will encourage flotation out of the right ventricle, as well as reduce the incidence of arrhythmias during insertion.[247,248] Deep inspiration during spontaneous ventilation will increase venous return and RV output transiently, and may facilitate catheter flotation in a patient with low cardiac output. On occasion, a catheter may be floated to

BOX 36.7 **Complications of Pulmonary Artery Catheter Monitoring**

Catheterization
  - Arrhythmias, ventricular fibrillation
  - Right bundle branch block, complete heart block (if preexisting left bundle branch block)

Catheter residence
  - Mechanical: catheter knots, entangling with or dislodgement of pacing wires
  - Thromboembolism
  - Pulmonary infarction
  - Infection, endocarditis
  - Endocardial damage, cardiac valve injury
  - Pulmonary artery rupture
  - Pulmonary artery pseudoaneurysm

Misinterpretation of data
  - Misuse of equipment

proper position when stiffened by injecting 10 to 20 mL of ice cold solution through the distal lumen. Finally, maneuvering of the PAC can also be guided by transesophageal or transthoracic echocardiography, demonstrating the catheter passage through the right heart.[249,250]

COMPLICATIONS OF PULMONARY ARTERY CATHETER MONITORING

Complications of PAC use may be divided into those resulting from catheter placement, those associated with the *in-vivo* presence of the catheter, and those resulting from catheter use and misuse. For the most part, problems encountered during catheter placement are the same for both PAC and CVP monitoring (see Box 36.6). However, catheterization of the right ventricle and pulmonary artery causes complications uniquely associated with PACs (Box 36.7).[251]

When all adverse effects from PAC use are considered, including self-limited arrhythmias observed during catheter insertion, it appears that minor complications occur in more than 50% of catheterized patients.[252] However, major morbidity specifically attributable to PAC use is uncommon.[253] In both an initial exhaustive review of the literature and in its 2003 update, the ASA Task Force on Pulmonary Artery Catheterization emphasized that the reported incidence of complications from PAC monitoring varies widely, although it seems that serious complications occur in 0.1% to 0.5 % of PAC-monitored surgical patients.[252] In 1984, Shah et al. reported use of PACs in 6245 patients undergoing cardiac and noncardiac operations.[187] Quite remarkably, only 10 patients (0.16%) had serious complications resulting in morbidity and only 1 patient (0.016%) died as a result of PAC. Furthermore, a 1998 European report of PAC use in 5306 patients undergoing cardiac surgery confirms this low incidence of major morbidity, with injury of the right ventricle or PA occurring in only 4 patients (0.07%).[254] Finally, only 1 of 2000 adverse events reported in the Australian Incident Monitoring Study of 1993 involved use of a PAC, in contrast to 64 adverse events involving access to the arterial or venous systems.[99] However, it is important to acknowledge that although these large studies indicate a low incidence of serious complications attributable to the use of PACs, the frequency of complications in a particular clinical setting or patient group remains unknown.

A more insidious but possibly more common complication of PAC use is **misinterpretation of data**.[255,256] Although the magnitude of the problem is not clear, studies show widespread knowledge deficits among practitioners who use PACs. In 1990, Iberti and associates reported the results of a 31-question multiple-choice examination given to 496 physicians. They found a poor overall level of knowledge of PACs, as evidenced by a mean score of only 67% correct answers. Although higher scores were demonstrated by individuals with more training and more experience inserting and using PACs, none of these factors ensured a high level of knowledge.[257] These results have been duplicated in a variety of other specialty care groups.[258] It is especially concerning that PAWP measurement was performed incorrectly by 30% to 50% of the clinicians in these studies and that educational programs failed to improve performance.[259,260] Taken together, these observations highlight the fact that effective use of PACs requires a great deal of expertise and clinical experience, and even measuring the most fundamental PAC-derived variable, namely wedge pressure, is a complicated endeavor.[261]

NORMAL PULMONARY ARTERY PRESSURES AND WAVEFORMS

As the balloon-tipped PAC is floated to its proper position in the pulmonary artery, characteristic pressure waveforms are recorded (see Fig. 36.38). In the superior vena cava or right atrium, a CVP waveform with characteristic a-, c-, and v waves and low mean pressure should be observed. RV pressure is characterized by a rapid systolic upstroke, a wide pulse pressure, and low diastolic pressure. Entry of the PAC into the pulmonary artery is heralded by a step-up in diastolic pressure and a change in waveform morphology.

On occasion, it may be difficult to distinguish RV pressure from PAP, particularly if only the numeric values for these pressures are examined. However, careful observation of the pressure waveforms, focusing on the diastolic pressure contours, allows differentiation. During diastole, the PAP will fall owing to continuous runoff flow to the lung, while the pressure in the right ventricle will increase due to filling from the right atrium (see Fig. 36.38).[262]

As noted above, the wedge pressure is an indirect measurement of pulmonary venous pressure and left atrial pressure and should therefore resemble these venous waveforms with characteristic a and v waves and x and y descents. However, owing to the pulmonary vascular bed interposed between the PAC tip and left atrium, wedge pressure is a delayed and damped representation of left atrial pressure.[263]

The terms PAWP and pulmonary artery occlusion pressure are used interchangeably and refer to the same measurement obtained from the tip of a PAC following balloon inflation and flotation to the wedged position. However, pulmonary capillary pressure must not be confused with wedge pressure or left atrial pressure, nor should the term *pulmonary capillary wedge pressure* be used at all. The hydrostatic pressure in the pulmonary capillaries that causes edema formation according to the Starling equation is different from left arterial pressure (LAP). This is the pressure that must exceed

LAP in order to maintain antegrade blood flow through the lungs. Although the magnitude of the difference between pulmonary capillary pressure and wedge pressure is generally small, it can increase markedly when resistance to flow in the pulmonary veins is elevated.[264] In most situations, the major component of pulmonary vascular resistance occurs at the precapillary, pulmonary arteriolar level. However, rare conditions like pulmonary venoocclusive disease may cause a marked increase in postcapillary resistance to flow. Similar situations arise in conditions that disproportionately increase pulmonary venous resistance, such as central nervous system injury, acute lung injury, hypovolemic shock, endotoxemia, and norepinephrine infusion.[265,266] Under these conditions, measurement of wedge pressure will underestimate pulmonary capillary pressure substantially and thereby underestimate the risk of hydrostatic pulmonary edema.

ABNORMAL PULMONARY ARTERY AND WEDGE PRESSURE WAVEFORMS

PAC monitoring is subject to the same technical artifacts inherent in all invasive pressure monitoring techniques as well as some additional problems unique to this method.[267-269] Because the PAC is longer and passes through the cardiac chambers, it is more prone to distortions from clot or air bubbles, and motion-related artifacts are more problematic. Artifactual pressure spikes may be distinguished from the underlying physiologic pressure waveform by their unique morphology and timing.

At the onset of systole, tricuspid valve closure accompanied by RV contraction and ejection result in excessive **catheter motion** causing the most common PAC trace artifact.[268,270] This pressure artifact may produce an artificially low pressure, erroneously designated as the pulmonary artery diastolic (PAD) pressure (Fig. 36.39). Repositioning the PAC often solves the problem.

Another common artifact in PAC pressure measurement occurs when the balloon is overinflated and occludes the distal lumen orifice. This phenomenon is termed **overwedging** and usually is caused by distal catheter migration and eccentric balloon inflation that forces the catheter tip against the vessel wall. The catheter now records a gradually rising, non-pulsatile pressure as the continuous flush system builds up pressure against the obstructed distal opening (Fig. 36.40). When observed, this should be corrected immediately by gentle catheter withdrawal to a more proximal location in the pulmonary artery.

As emphasized earlier, with each PAC balloon inflation and wedge measurement, the catheter tip migrates distally. When a wedge pressure tracing appears during partial balloon inflation, it suggests that the PAC is inappropriately located in a smaller, distal branch of the pulmonary artery. The catheter should be withdrawn slightly before overwedging can occur and result in vascular injury or pulmonary infarction.

Pathophysiologic conditions involving the left-sided cardiac chambers or valves produce characteristic changes in the pulmonary artery and wedge pressure waveforms. One of the most easily recognized patterns is the tall v wave of **mitral regurgitation**. Unlike a normal wedge pressure v wave produced by late systolic pulmonary venous inflow, the prominent v wave of mitral regurgitation begins in early systole. Mitral regurgitation causes fusion of c and v waves and obliteration of the systolic x descent, as the isovolumic phase of LV systole is eliminated owing to the retrograde ejection of blood into the left atrium.[237] Because the prominent v wave of mitral regurgitation is generated during

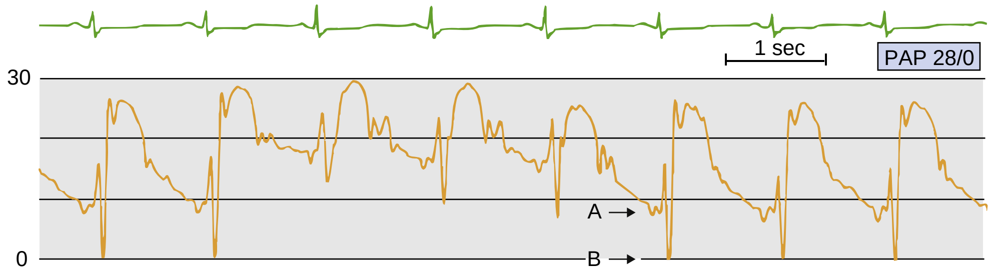

Fig. 36.39 Artifactual pressure peaks and troughs in the pulmonary artery pressure *(PAP)* waveform caused by catheter motion. The correct value for pulmonary artery end-diastolic pressure is 8 mm Hg (A), although the monitor digital display erroneously reports the PAP as 28/0 mm Hg (B). (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

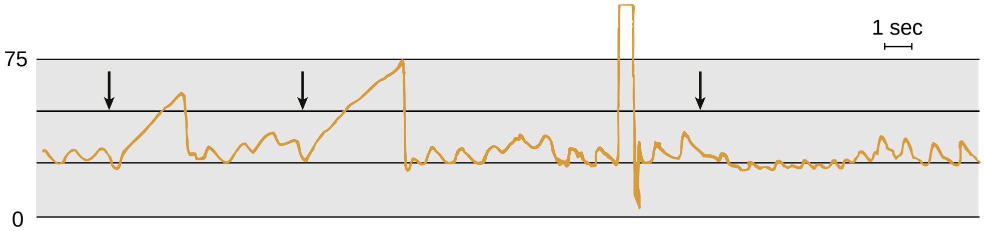

Fig. 36.40 Overwedging of the pulmonary artery (PA) catheter causes artifactual waveform recordings. The first two attempts to inflate the PA catheter balloon *(first two arrows)* produce a nonpulsatile increasing pressure caused by an occluded catheter tip. After the catheter is withdrawn slightly, balloon inflation allows proper wedge pressure measurement *(third arrow)*. Before the third attempt at balloon inflation, the PA pressure lumen is flushed. This restores the appropriate pulsatile nature to the PA and wedge pressure waveforms on the right side of the trace. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

ventricular systole, the mean wedge pressure overestimates LV end-diastolic filling pressure, which is better estimated by the pressure value prior to onset of the regurgitant v wave (Fig. 36.41). However, it remains a good approximation for mean left atrial pressure and the subsequent risk of hydrostatic pulmonary edema.

It should be noted that although the height of the v wave in the wedge pressure trace will be affected by the volume of regurgitant blood entering the left atrium, it also depends on the left atrial volume and compliance (Fig. 36.42). This may explain why patients with acute mitral regurgitation tend to have tall wedge pressure v waves—they have smaller, stiffer left atria with poorer compliance compared to patients with longstanding disease. Therefore, the height of the wedge pressure v wave is neither a sensitive nor a specific indicator of mitral regurgitation severity.[271]

In contrast to mitral regurgitation, which distorts the systolic portion of the wedge pressure waveform, **mitral stenosis** alters its diastolic aspect. In this condition, the holo-diastolic pressure gradient across the mitral valve results in an increased mean wedge pressure, a slurred early diastolic y descent, and a tall end-diastolic a wave. Similar hemodynamic abnormalities are seen in patients with left atrial myxoma or whenever there is obstruction to mitral flow. Diseases that increase LV stiffness (e.g., LV infarction, pericardial constriction, aortic stenosis, and systemic hypertension) produce changes in the wedge pressure that resemble in part those seen in mitral stenosis. In these conditions, mean wedge pressure is increased and the trace displays a prominent a wave, but the y descent remains steep because there is no obstruction to flow across the mitral valve during diastole. Because patients with advanced mitral stenosis often have coexisting atrial fibrillation, the a wave will not be present in many of these cases (Fig. 36.43).[237]

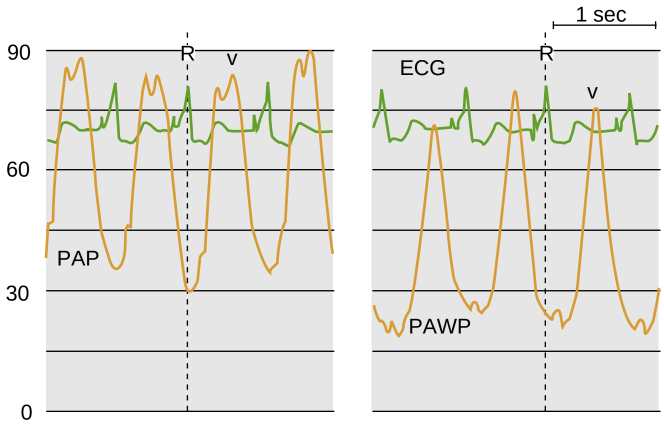

Fig. 36.41 Severe mitral regurgitation. A tall systolic v wave *(v)* is inscribed in the pulmonary artery wedge pressure *(PAWP)* trace and also distorts the pulmonary artery pressure *(PAP)* trace, giving it a bifid appearance. The electrocardiogram *(ECG)* is abnormal owing to ventricular pacing. Left ventricular end-diastolic pressure is estimated best by measuring PAWP at the time of the electrocardiographic R wave, before onset of the regurgitant v wave. Note that mean PAWP exceeds left ventricular end-diastolic pressure in this condition. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

Myocardial ischemia may be detected by PAC in several ways. Ischemia itself impairs LV relaxation resulting in diastolic dysfunction, a pattern particularly characteristic of demand ischemia associated with tachycardia or induced by rapid atrial pacing.[227,272,273] Impaired ventricular relaxation results in a stiffer, less compliant left ventricle, resulting in an increased LV end-diastolic pressure. This will result in a tall a wave on the wedge trace, as the left atrium contracts into a stiff, incompletely relaxed left ventricle (Fig. 36.44).[274]

Myocardial ischemia can also produce LV systolic dysfunction, typically as a result of supply ischemia, caused by a sudden reduction or cessation of coronary blood flow to a region of the myocardium.[273,275] As ejection fraction falls significantly, LV end-diastolic volume and pressure rise, and elevated pulmonary diastolic and wedge pressures develop.[276] Distortion of LV geometry or ischemia of the myocardium underlying the papillary muscles can lead to acute mitral regurgitation with its characteristic PAP trace changes described above (see Fig. 36.41).[277]

Whether the PAC should be used in high-risk patients as a supplemental monitor for detection of myocardial ischemia remains controversial. Although patients with LV ischemia are likely to have higher mean wedge pressures than those without ischemia, these differences are small, may be difficult to detect clinically, and no clear quantitative threshold values for diagnosis of ischemia have been identified.[278]

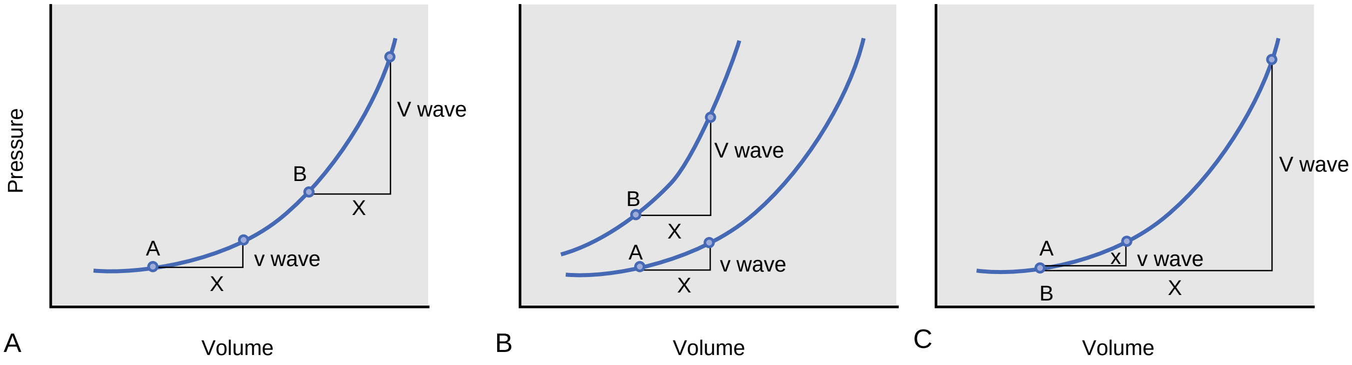

Fig. 36.42 V-wave height as an indicator of mitral regurgitation severity. Left atrial pressure-volume curves describe the three factors that determine v-wave height. (A) Influence of left atrial volume. For the same regurgitant volume (X), the left atrial v wave will be taller if baseline atrial volume is greater (point B versus point A). (B) Influence of left atrial compliance. For the same regurgitant volume (X), the left atrial v wave will be taller if baseline atrial compliance is reduced (point B versus point A). (C) Influence of regurgitant volume. Beginning at the same baseline left atrial volume (points A and B), if regurgitant volume increases (X versus x), the left atrial pressure v wave will increase (V versus v). (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

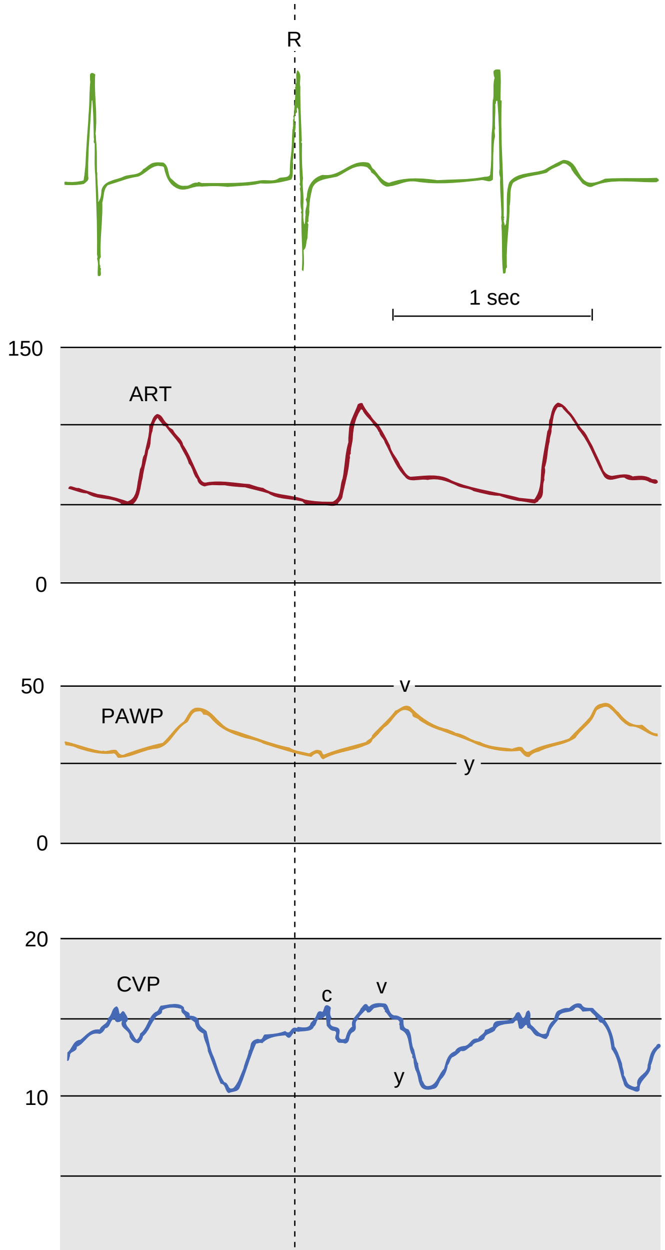

Fig. 36.43 Mitral stenosis. Mean pulmonary artery wedge pressure *(PAWP)* is increased (35 mm Hg), and the diastolic y descent is markedly attenuated. Compare the slope of the y descent in the PAWP trace with the y descent in the central venous pressure *(CVP)* trace. In addition, compare this PAWP y descent with the PAWP y descent in mitral regurgitation (see Figure 36.41); a waves are not seen in the PAWP or CVP traces, owing to atrial fibrillation. *ART,* Arterial blood pressure. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

Right ventricular ischemia produces characteristic PAC waveform patterns that may be helpful in diagnosis and management. Just as LV ischemia increases PAWP, RV ischemia increases CVP. In fact, this is one of the few situations in which CVP may be higher than wedge pressure. In addition, CVP waveforms may display a prominent a wave resulting from RV diastolic dysfunction, and a prominent v wave resulting from ischemia-induced tricuspid regurgitation.[279,280] This particular CVP waveform is described as having an M or W configuration, referring to the tall a and v waves and interposed steep x and y descents. Severe pulmonary artery hypertension may also result in RV ischemia and dysfunction as well as increased CVP, but this is distinguished from primary RV dysfunction in that the PAP and calculated pulmonary vascular resistance are normal in primary RV failure.

The CVP waveform in RV infarction is similar to that from a patient with restrictive cardiomyopathy or **pericardial constriction**, including elevated mean pressure, prominent a and v waves, and steep x and y descents.[281] The cardinal feature common to these conditions is impaired RV diastolic compliance, often termed “restrictive physiology.” In restrictive cardiomyopathy and RV infarction, diastolic dysfunction impairs ventricular relaxation and decreases chamber compliance, whereas in constrictive pericarditis cardiac filling is limited by the rigid, often calcified pericardial shell. Impaired venous return decreases end-diastolic volume, stroke volume, and cardiac output. Despite reduced cardiac volumes, cardiac filling pressures are markedly elevated and equal in all four chambers of the heart at end-diastole (Fig. 36.45). Although PAC monitoring reveals this pressure equalization, the characteristic M or W configuration is more apparent in the CVP trace, most likely because of the damping effect of the pulmonary vasculature on the left-sided filling pressures.[282-284]

Another hallmark of pericardial constriction is observed in the right and LV pressure traces. These demonstrate rapid but short-lived early diastolic ventricular filling, which produces a diastolic “dip-and-plateau” pattern or “square root sign.”[129,285] In some cases, particularly when heart rate is slow, a similar waveform pattern may be noted in the CVP trace: a steep y descent (the diastolic dip) produced by rapid early diastolic flow from atrium to ventricle, followed by a mid-diastolic h wave (the plateau) from the interruption in flow imposed by the restrictive pericardial shell (see Fig. 36.45).

Like pericardial constriction, **cardiac tamponade** impairs cardiac filling, but in the case of tamponade, a compressive pericardial fluid collection produces this effect. This results in a marked increase in CVP and a reduced diastolic volume, stroke volume, and cardiac output. Despite many similar hemodynamic features, tamponade and constriction may be distinguished by the different CVP waveforms seen in these two conditions. In tamponade, the venous pressure waveform appears more monophasic and is dominated by the systolic x pressure descent. The diastolic y pressure descent is attenuated or absent, because early diastolic flow from right atrium to right ventricle is impaired by the surrounding compressive pericardial fluid collection (Fig. 36.46).[282,286,287] Clearly, other clinical and hemodynamic clues help distinguish these diagnoses, such as the presence of *pulsus paradoxus*, an almost invariable finding in cardiac tamponade (see Fig. 36.32).[288]

Probably the single most important waveform abnormality or interpretive problem in PAC monitoring is discerning the correct pressure measurement in patients with large intrathoracic pressure swings like those receiving **positive pressure ventilation** or those with labored spontaneous breathing. During positive pressure ventilation, inspiration increases pulmonary artery and wedge pressures. By measuring these pressures at end-expiration, the confounding

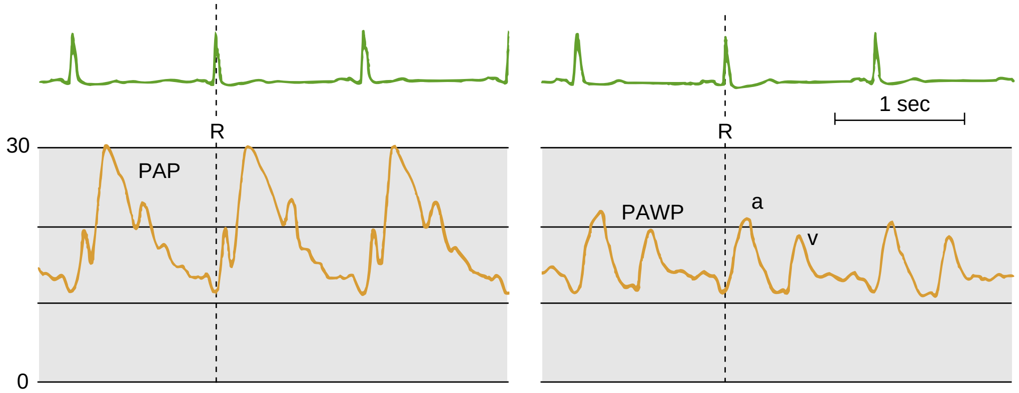

Fig. 36.44 Myocardial ischemia. Pulmonary artery pressure *(PAP)* is relatively normal and mean pulmonary artery wedge pressure *(PAWP)* is only slightly elevated (15 mm Hg). However, PAWP morphology is markedly abnormal with tall a waves (21 mm Hg) resulting from the diastolic dysfunction seen in this condition. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

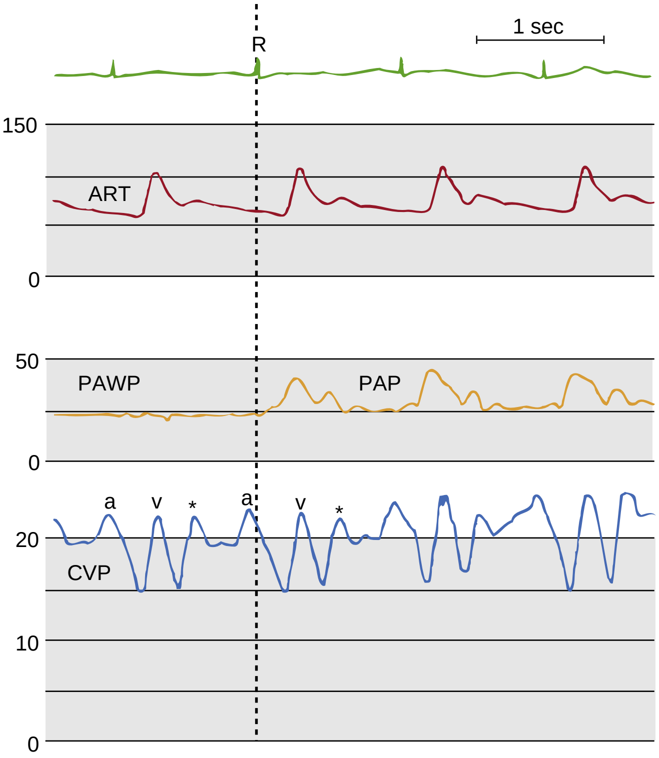

Fig. 36.45 Pericardial constriction. This condition causes elevation and equalization of diastolic filling pressures in the pulmonary artery pressure *(PAP)*, pulmonary artery wedge pressure *(PAWP)*, and central venous pressure *(CVP)* traces. The CVP waveform reveals tall a and v waves with steep x and y descents and a mid-diastolic plateau wave (*) or h wave. *ART*, Arterial blood pressure. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

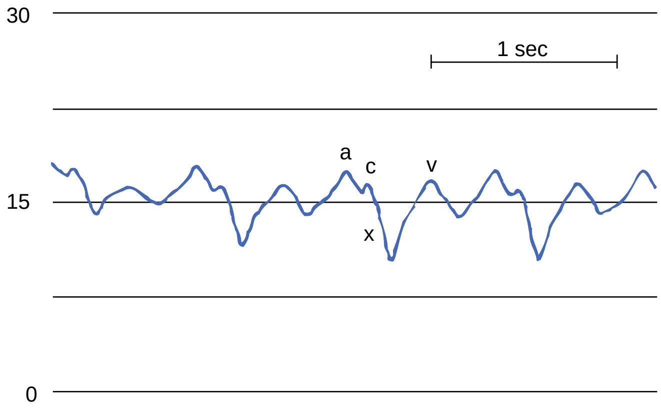

Fig. 36.46 Cardiac tamponade. The central venous pressure waveform shows an increased mean pressure (16 mm Hg) and attenuation of the y descent. Compare with Figure 36.45. (From Mark JB. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998.)

effect of this inspiratory increase in intrathoracic pressure is minimized (Fig. 36.47).[228] Forceful inspiration during spontaneous ventilation has the opposite effect, but again, measurement of these pressures at end-expiration eliminates this confounding factor. Bedside monitors are designed with algorithms that aim to identify and report the numeric values for end-expiratory pressures but are often inaccurate.[289,290] The most reliable method for measuring central vascular pressures at end-expiration is examination of the waveforms on a calibrated monitor screen or paper recording.[290,291]

PHYSIOLOGIC CONSIDERATIONS FOR PULMONARY ARTERY CATHETER MONITORING: PREDICTION OF LEFT VENTRICULAR PRELOAD

One reason to measure PAD and wedge pressures is to be able to estimate LV end-diastolic pressure, the closest surrogate to LV end-diastolic volume, which is the true LV preload. When a PAC floats to the wedge position, the inflated balloon isolates the distal pressure-monitoring orifice from upstream PAP. A continuous static column of blood now connects the wedged PAC tip to the junction of the pulmonary veins and left atrium. Thus, wedging the PAC, in effect, extends the catheter tip to measure the pressure at the point at which blood flow resumes on the venous side of the pulmonary circuit. Because resistance in the large pulmonary veins is negligible, PAWP provides an indirect measurement of both pulmonary venous pressure and left atrial pressure.[292,293] For the column of blood connecting the tip of the wedged catheter and the draining pulmonary vein to be continuous, however, external compression by surrounding alveoli should be negligible (i.e., the catheter needs to reside in the so-called West zone 3 of the lung) (Fig. 36.48). [293]

PAD pressure is often used as an alternative to PAWP to estimate LV filling pressure. This is acceptable under normal circumstances because when pulmonary venous

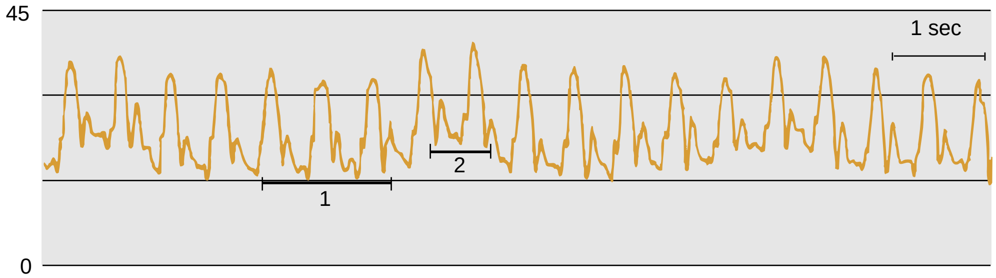

Fig. 36.47 Influence of positive-pressure mechanical ventilation on pulmonary artery pressure. Pulmonary artery pressure should be measured at end expiration (*1*, 15 mm Hg) in order to obviate the artifact caused by positive-pressure inspiration (*2*, 22 mm Hg). (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

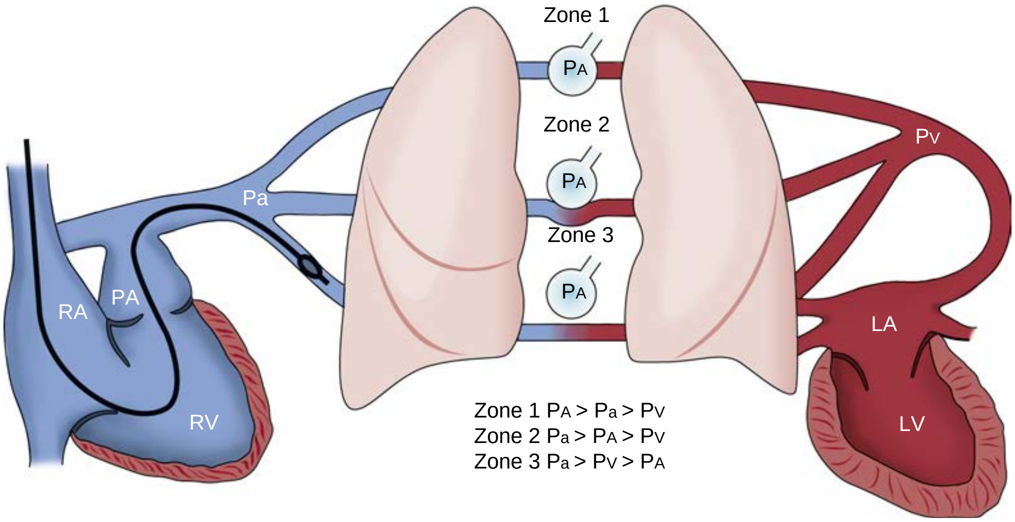

Fig. 36.48 The pulmonary artery catheter tip must be wedged in lung zone 3 to provide an accurate measure of pulmonary venous *(Pv)* or left atrial *(LA)* pressure. When alveolar pressure *(P_A)* rises above Pv in lung zone 2, or above pulmonary arterial pressure *(Pa)* in lung zone 1, wedge pressure will reflect alveolar pressure rather than intravascular pressure. *RA*, Right atrium; *RV*, right ventricle; *PA*, pulmonary artery; *LV*, left ventricle. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998, Fig. 6–10.)

resistance is low, the pressure in the pulmonary artery at end of diastole will equilibrate with downstream pressure in the pulmonary veins and left atrium.[294,295] From a monitoring standpoint, PAD has the added advantage of being available for continuous monitoring whereas PAWP is only measured intermittently.

In many situations, LV end-diastolic pressure can be either underestimated or overestimated by the PAWP and/or PAD. These situations are summarized in Figure 36.49 and Tables 36.5 and 36.6. The interested reader is referred to several excellent references for further discussion of this topic.[292,293,296]

However, even when PAD and wedge pressure accurately estimate LV end-diastolic pressure, many factors can influence the relationship between end-diastolic pressure and end-diastolic chamber volume, which is the true preload. Proper interpretation of filling pressures requires assessment of juxtacardiac pressure as well as ventricular compliance. When both are normal, a wedge pressure of 20 mm Hg is interpreted as hypervolemia, with an increased LV end-diastolic volume causing the increased PAWP. However, if juxtacardiac pressure is increased (e.g., due to cardiac tamponade, pericardial constriction, or positive pressure ventilation), or ventricular compliance is decreased (e.g., with myocardial ischemia, hypertrophy, or cardiomyopathy), a wedge pressure of 20 mm Hg can coexist with a small, hypovolemic left ventricle (Fig. 36.50).

In addition, ventricular interdependence (caused by the shared septum of the left and right ventricles) and pericardial constraint couple changes in RV and LV function. For example, acute pulmonary arterial hypertension increases RV end-diastolic volume and pressure, and shifts the ventricular septum leftward, thus increasing LV end-diastolic pressure while simultaneously decreasing LV end-diastolic volume. Conversely, primary changes on the left side can adversely affect the right heart structures in similar ways. With all these considerations in mind, it should be of no surprise that various studies have repeatedly shown that both CVP and PAWP may not always correlate with cardiac preload and do not necessarily predict the cardiac output response to a fluid challenge.[238,297] In contrast, in patients with systolic ventricular dysfunction, filling pressures were found more accurate than cardiac volume indices in predicting fluid responsiveness.[298]

PULMONARY ARTERY CATHETER-DERIVED HEMODYNAMIC VARIABLES

The cardiovascular system is often modeled as an electrical circuit, with the relationship between cardiac output, blood

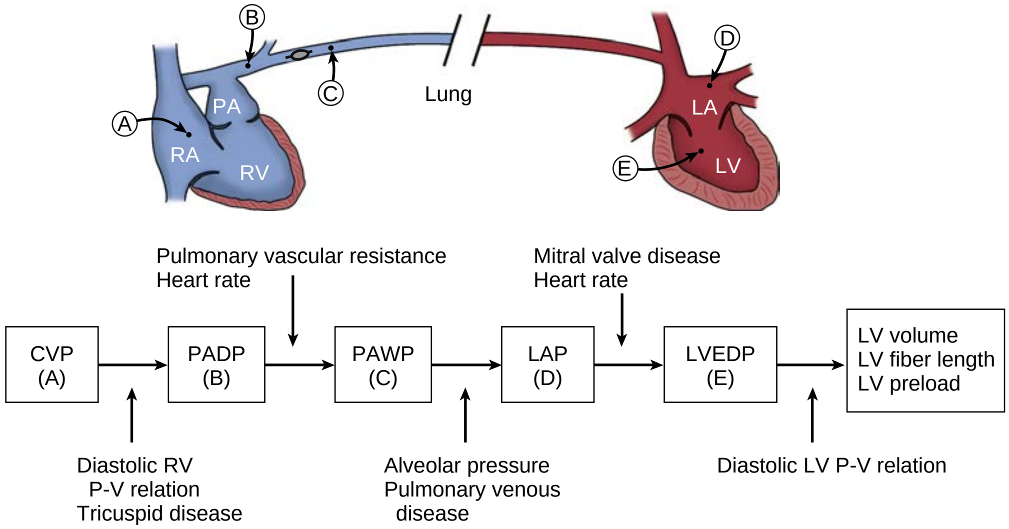

Fig. 36.49 Anatomic and physiologic factors that influence the relations between various measures of left ventricular *(LV)* filling and true LV preload. The further upstream the filling pressure is measured, the more confounding factors may influence the relation between this measurement and LV preload. *CVP*, Central venous pressure; *LA*, left atrium; *LAP*, left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PA*, pulmonary artery; *PADP*, pulmonary artery diastolic pressure; *PAWP*, pulmonary artery wedge pressure; *P-V*, pressure-volume; *RA*, right atrium; *RV*, right ventricle. TABLE 36.5 Underestimation of Left Ventricular End-Diastolic Pressure

Condition	Site of Discrepancy	Cause of Discrepancy
Diastolic dysfunction	Mean LAP <LVEDP	Increased end-diastolic a wave
Aortic regurgitation	LAP a wave <LVEDP	Mitral valve closure before end-diastole
Pulmonic regurgitation	PADP <LVEDP	Bidirectional runoff for pulmonary artery flow
Right bundle branch block	PADP <LVEDP	Delayed pulmonic valve opening
Post-pneumonectomy	PAWP <LAP or LVEDP	Obstruction of pulmonary blood flow

LAP, Left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PADP*, pulmonary artery diastolic pressure; *PAWP*, pulmonary artery wedge pressure.
Modified from Mark JB. Predicting left ventricular end-diastolic pressure. In: Mark JB, ed. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998:59.

TABLE 36.6 Overestimation of Left Ventricular End-Diastolic Pressure

Condition	Site of Discrepancy	Cause of Discrepancy
Positive end-expiratory pressure	Mean PAWP >Mean LAP	Creation of lung zone 1 or 2, or pericardial pressure changes
Pulmonary arterial hypertension	PADP >Mean PAWP	Increased pulmonary vascular resistance
Pulmonary venoocclusive disease	Mean PAWP >Mean LAP	Obstruction to flow in large pulmonary veins
Mitral stenosis	Mean LAP >LVEDP	Obstruction to flow across mitral valve
Mitral regurgitation	Mean LAP >LVEDP	Retrograde systolic v wave raises mean atrial pressure
Ventricular septal defect	Mean LAP >LVEDP	Antegrade systolic v wave raises mean atrial pressure
Tachycardia	PADP >Mean LAP >LVEDP	Short diastole creates pulmonary vascular and mitral valve gradients

LAP, Left atrial pressure; *LVEDP*, left ventricular end-diastolic pressure; *PADP*, pulmonary artery diastolic pressure; *PAWP*, pulmonary artery wedge pressure.
Modified from Mark JB. Predicting left ventricular end-diastolic pressure. In: Mark JB, ed. *Atlas of Cardiovascular Monitoring.* New York: Churchill Livingstone; 1998:59.

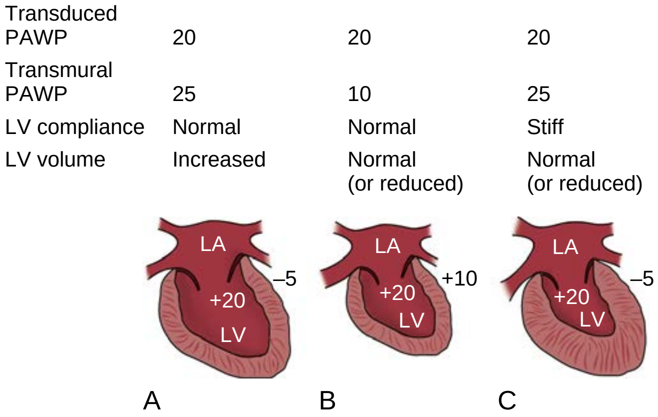
pressure, and resistance to flow related in a manner similar to Ohm's law:

$$\text{PVR} = \frac{\text{MPAP} - \text{PAWP}}{\text{CO}} \bullet (80)$$

$$\text{SVR} = \frac{\text{MAP} - \text{CVP}}{\text{CO}} \bullet (80) \qquad (36.1)$$

Where,
SVR = systemic vascular resistance (dyne•s/cm^5)
PVR= pulmonary vascular resistance (dyne•s/cm^5)
MAP = mean arterial pressure (mm Hg)
CVP = central venous pressure (mm Hg)
MPAP = mean pulmonary artery pressure (mm Hg)
PAWP = pulmonary artery wedge pressure (mm Hg)
CO = cardiac output (L/min)

Normal values for SVR and PVR are given in Table 36.7. Note that these calculations of systemic and pulmonary vascular resistance are based on a hydraulic fluid model that assumes continuous, laminar flow through a series of rigid pipes.[299] This is an oversimplification. A more physiologic model of the systemic circulation considers the vasculature to be a series of collapsible vessels with intrinsic tone. This model, also called the vascular waterfall, describes a critical closing pressure in the downstream end of the circuit that exceeds right atrial pressure and serves to limit flow—an effective downstream pressure that is higher than the right



Transduced PAWP	20	20	20
Transmural PAWP	25	10	25
LV compliance	Normal	Normal	Stiff
LV volume	Increased	Normal (or reduced)	Normal (or reduced)

Fig. 36.50 Influence of juxtacardiac pressure and ventricular compliance on left ventricular *(LV)* preload. Three interpretations of an increased transduced pulmonary artery wedge pressure (*PAWP*, 20 mm Hg) are possible. (A) Juxtacardiac pressure (–5 mm Hg) and LV compliance are normal, transmural PAWP is increased (25 mm Hg), and LV volume is increased. (B) Juxtacardiac pressure is increased (+10 mm Hg), LV compliance is normal, transmural PAWP is decreased (10 mm Hg), and LV volume is normal or decreased. (C) Juxtacardiac pressure is normal, LV compliance is decreased, transmural PAWP is increased (25 mm Hg), and LV volume is normal or decreased. *LA*, Left atrial. (From Mark JB. *Atlas of Cardiovascular Monitoring*. New York: Churchill Livingstone; 1998.)

atrial pressure used in the SVR formula. A detailed consideration of these issues is beyond the scope of this discussion and is available in other sources.[300,301] The important point for clinicians, though, is that therapy focused on the fine adjustment of SVR may be very misleading and should be avoided.

Additional problems arise in considering the pulmonary vasculature and using the above formulae as a measure of resistance to flow through the lung.[302] The pulmonary vasculature is more compliant than the systemic vasculature, and marked increases in pulmonary blood flow may not produce any significant increase in PAP. In addition, flow usually ceases at end-diastole in the low resistance pulmonary circuit. Thus, changes in pulmonary vascular resistance may result from intrinsic alterations in pulmonary vascular tone (constriction or dilation), vascular recruitment, or rheologic changes. For the pulmonary circuit, a better approach to evaluating the changes in pulmonary vascular resistance may be to examine the pressure gradient between the PAD and wedge pressures, or the gradient between the mean pulmonary artery and wedge pressures (also termed the trans-pulmonary gradient).

TABLE 36.7 Normal Hemodynamic Values

	Average	Range
Cardiac output (L/min)	5.0	4.0-6.5
Stroke volume (mL)	75	60-90
Systemic vascular resistance (Wood units) (Dynes-sec-cm^{-5})	1200	800-1600
Pulmonary vascular resistance (Wood units) (Dynes-sec-cm^{-5})	80	40-180
Arterial oxygen content (mL/dL)	18	16-20
Mixed venous oxygen content (mL/dL)	14	13-15
Mixed venous oxygen saturation (%)	75	70-80
Arteriovenous oxygen difference (mL/dL)	4	3-5
Oxygen consumption (mL/min)	225	200-250

Another set of common calculations derived from standard hemodynamic variables adjusts these measurements for the patient's body surface area (BSA) in an attempt to normalize these measurements for patients of different sizes. The BSA is generally determined from a standard nomogram based on height and weight. The most commonly indexed variables are the cardiac index (cardiac index = cardiac output/body surface area) and stroke volume index (stroke volume index = stroke volume/body surface area). On occasion, the systemic and pulmonary vascular resistances are indexed as well by multiplying by BSA. In theory, normalizing hemodynamic values through "indexing" should help clinicians determine appropriate normal physiologic ranges to help guide therapy. Unfortunately, there is little evidence that these additional calculations provide valid normalizing adjustments. BSA is a biometric measurement with an obscure relationship to blood flow and cardiac output, and it does not adjust for variations between individuals based on age, sex, body habitus, or metabolic rate.[303] Although it is important to be aware of a patient's size and medical history in interpreting and treating changes in any of the measured or calculated hemodynamic variables, it is not appropriate to target therapy solely at achieving normal indexed values.

PULMONARY ARTERY CATHETERIZATION: INDICATIONS AND OUTCOME CONTROVERSY

The PAC allows continuous tracking of hemodynamic variables, which seems particularly valuable in critically ill high-risk patients with circulatory dysfunction. Measurement of cardiac output (see below section on Thermodilution cardiac output) can separate shock states into hypovolemic etiology (low cardiac output with low filling pressures), cardiogenic etiology (low cardiac output and high filling pressures), and distributive etiology (high cardiac output and low SVR). Through measurement of cardiac output and left and right filling pressures (PAWP and CVP, respectively), it can separate out predominantly LV or RV dysfunction or global dysfunction. For RV dysfunction, the PAC allows distinction of RV dysfunction predominantly related to increased afterload (high PAP) versus dysfunction related mostly to pump failure (high CVP and low PAP).[304,305]

Despite these advantages, the PAC has stimulated a great deal of vigorous controversy.[306,307] It is an expensive, invasive technique that is widely used but still not proven to improve patient outcomes. This controversy was much fueled by a study published by Connors and associates in 1996, showing that PAC-monitored patients in the ICU had 20% increased mortality, increased length of hospital stay, and incurred increased costs.[308] The publication of this study was accompanied by a strongly worded editorial calling for a moratorium on PAC use or a randomized controlled trial to define its efficacy.[309]

Surrounding that time and in subsequent years, several large, randomized, adequately powered studies have been published regarding the use of the PAC in various settings: general non-cardiac surgery,[244] vascular surgery,[310] CABG surgery,[311,312] non-surgical patients with congestive heart failure,[313] patients with acute lung injury,[314] and critically ill patients in the ICU.[315] Generally, these studies have shown no benefit to PAC use, but also no increase in mortality or in hospital or ICU length of stay.

One common drawback to most of these large randomized studies is that they have necessarily examined the routine use of PAC and enrolled a sequential cohort of patients, most of them with a relatively moderate risk of death or complications. Also, not all of them have employed a specific therapeutic intervention protocol.[316] Indeed, in especially high-risk patients, marked either by old age, severe comorbidity, or increased disease acuity, several recent nonrandomized studies were indeed able to demonstrate a clinical benefit from PAC use.[317-320]

The most recent recommendations pertaining to the perioperative use of PACs are the ASA practice guidelines published in 2003.[252] The task force considered PAC monitoring to be appropriate in high-risk surgical patients undergoing high-risk procedures. Furthermore, the specific practice setting as well as the proficiency and experience of clinicians should be considered.

PAC use must be tailored to the degree of risk for the patient and the risk posed by the procedure itself. For example, a patient with advanced ischemic cardiomyopathy who needs lower extremity amputation under regional anesthesia would not warrant PAC monitoring while a patient with stable ischemic heart disease scheduled for extensive abdominal cancer resection may benefit from perioperative use. Furthermore, practice setting must be considered such as the operators' technical skill, knowledge, and experience in PAC use.[252]

A reasonable conclusion from the bulk of published research would be that PAC use should be limited, although a moratorium on use is ill-advised. Indeed, data demonstrate a significant and continuing decrease in PAC usage.[321] Use should be reserved to centers with significant experience and expertise. The PAC generally should be used to monitor and guide therapy in patients at high risk for hemodynamic instability, those who are judged more critically ill by a variety of clinical means, and those who are in shock, especially if elderly and suffering from other systemic diseases.

Obviously, the PAC itself has no potential for benefit unless it guides therapies that improve patient outcomes. Future research should focus on defining subgroups of patients who might benefit from use of the PAC, as well as defining effective therapeutic interventions based on the hemodynamic information gained from the PAC.[316,322,323] Heart failure patients in shock are one such population for which data from clinical registries suggest benefit despite lack of confirmatory evidence from randomized trials.[323,324]

SPECIAL TYPES OF PULMONARY ARTERY CATHETERS

Specific PAC modifications were designed to allow for continuous cardiac output (CCO) measurement (described in the Cardiac Output section), mixed venous oxygen saturation monitoring, or right heart function evaluation, vastly expanding the types of physiologic information available to those caring for critically ill patients.

Mixed Venous Oximetry Pulmonary Artery Catheter

Although the formal Fick cardiac output method is not widely applied in clinical practice outside the cardiac catheterization laboratory, the physiologic relations described by the Fick equation form the basis for another PAC-based monitoring technique termed continuous mixed venous oximetry.[325] Rearrangement of the Fick equation reveals the four determinants of mixed venous hemoglobin saturation ($S_{\bar{v}}O_2$):

$$S_{\bar{v}}O_2 = S_aO_2 - \frac{\dot{V}O_2}{\dot{Q} \bullet 1.36 \bullet \text{Hgb}} \qquad (36.2)$$

Where,

$S_{\bar{v}}O_2$ = mixed venous hemoglobin saturation (%)
S_aO_2 = arterial hemoglobin saturation (%)
$\dot{V}O_2$ = oxygen consumption (mL•O_2/min)
$\dot{Q}$ = cardiac output (L/min)
Hgb = hemoglobin concentration (g/dL)

To the extent that arterial hemoglobin saturation, oxygen consumption, and hemoglobin concentration remain stable, mixed venous hemoglobin saturation may be used as an indirect indicator of cardiac output. Thus, when cardiac output falls, tissue oxygen extraction increases and the mixed venous blood will have a lower hemoglobin oxygen saturation. Monitoring this variable provides more comprehensive information about the balance of oxygen delivery and consumption by the body—not just the cardiac output value, but also the adequacy of that cardiac output compared to tissue oxygen requirements.[325] It is important to remember that mixed venous hemoglobin saturation values reflect global, whole-body measurement. Therefore, regionally inadequate blood flow and tissue oxygen delivery (like limb or intestinal ischemia) can coexist with a normal or high mixed venous hemoglobin saturation.

Although mixed venous hemoglobin saturation may be determined by intermittent blood sampling from the distal port of the PAC, a specially designed PAC can provide this information reliably and continuously. Fiberoptic bundles incorporated into the PAC determine the hemoglobin oxygen saturation in pulmonary artery blood based on the principles of reflectance oximetry using either a two or three wavelength system. A special computer connected to this PAC displays the mixed venous hemoglobin saturation continuously. The technology is typically incorporated into the standard PAC or the CCO PAC (see later), in the latter case providing both CCO and venous oximetry data. These catheters are calibrated at the bedside prior to use but may also be calibrated in vivo from a pulmonary artery blood gas sample. Recalibration every 24 hours is usually recommended due to a drift artifact.

Recently, the technology to continuously measure oxygen saturation has been incorporated into central venous catheters as well. These catheters measure central venous saturation, measured in the superior vena cava. Normally, this saturation is around 70% versus 75% in the pulmonary artery.[325] Low central venous saturation has been associated with increased complications both in trauma patients and in major surgery patients.[326,327]

The real value of measuring venous oxygen saturation lies in its ability to guide therapeutic interventions. Because one of the body's physiologic compensations for anemia is increased oxygen extraction, low venous hemoglobin saturation has been used to guide the need for blood transfusion.[328] Several studies have used venous hemoglobin saturation to guide interventions aimed at increasing cardiac output—a goal-directed approach. A study in patients undergoing cardiac surgery has shown better outcomes in patients randomized to protocol-driven interventions aimed at achieving mixed venous hemoglobin saturation above 70% (and blood lactate <2mg/dL).[329] Similarly, optimizing the central venous oxygen saturation has been shown to improve outcome in high-risk non-cardiac and off-pump cardiac surgical patients.[330,331] Although an early study showed similar benefit in patients with early sepsis,[332] a more recent study could not confirm these results.[333]

It is important to note that these studies have employed strict protocol-driven therapeutic interventions. In contrast, a large Veterans Affairs observational trial of 3265 cardiac surgical patients noted that 49% of patients received continuous mixed venous oximetry PACs, and use of this catheter was associated with increased cost but no better outcome than the standard PAC group.[334] In this study, however, no protocol was used to guide therapeutic interventions based on monitoring results.

Right Ventricular Ejection Fraction Pulmonary Artery Catheter

Although cardiovascular monitoring has focused predominantly on LV performance, in some instances RV dysfunction may be the more important factor limiting circulation. Patient populations at increased risk for RV dysfunction include those with chronic obstructive pulmonary disease, adult respiratory distress syndrome, pulmonary hypertension, and RV ischemia and infarction.[335]

Measurement of right ventricular ejection fraction (RVEF) with a specially designed PAC offers another method for evaluating RV function. This method uses a standard PAC equipped with a rapid response thermistor that detects and quantifies the small changes in pulmonary artery blood temperature that occur with each heartbeat, in a manner somewhat analogous to a standard CCO PAC. The cardiac output computer measures the residual fraction of thermal signal following each heart beat and derives the RVEF.[336] RV end-diastolic volume can be calculated from RVEF and stroke volume, and can be used as an index of RV preload. Clearly, all factors that confound standard thermodilution cardiac output measurement (described later) will also interfere with accurate determination of RVEF. In addition, because the temperature changes measured by the RVEF PAC are small beat-to-beat changes, the method will not work if the ECG R waves cannot be detected accurately, the R-R interval is short owing to tachycardia, or the cardiac rhythm is irregular.[337]

Clinical use of the RVEF PAC has been described in critically ill patients, especially in those with respiratory failure,[338,339] as well as intraoperatively during cardiac surgery, where a reduced RVEF has been noted following cardiopulmonary bypass, particularly in patients with preexisting right coronary artery obstruction.[340] However, as in the case of standard PAC monitoring, the benefit of RVEF PAC monitoring in terms of patient outcomes remains unproven.[252]

Cardiac Output Monitoring

Cardiac output is the total blood flow generated by the heart, and in a normal adult at rest ranges from 4.0 to 6.5 L/min. Measurement of cardiac output provides a global assessment of the circulation, and in combination with other hemodynamic measurements (heart rate, arterial blood pressure, CVP, PAP, and wedge pressure), it allows calculation of additional important circulatory variables, such as systemic and pulmonary vascular resistance and ventricular stroke work (see Table 36.7).

Three factors have driven efforts to measure cardiac output in clinical practice. The first is the recognition that in many critically ill patients, low cardiac output leads to significant morbidity and mortality.[341] Secondly, clinical assessment of cardiac output is often inaccurate; for example, seriously ill patients with decreased cardiac output might have normal systemic arterial blood pressures.[342] Finally, newer techniques for cardiac output measurement are becoming less invasive and thus might provide benefit to many patients without the attendant risks of invasive monitoring.[342,343] The advantages and disadvantages of each technique must be appreciated for proper clinical application.

THERMODILUTION CARDIAC OUTPUT MONITORING

The thermodilution technique is considered the gold standard for measuring cardiac output because of its ease of implementation and the long clinical experience with its use in various settings. It is a variant of the **indicator dilution** method, in which a known amount of a tracer substance is injected into the blood stream and its concentration change is measured over time at a downstream site.[344] For thermodilution, a known volume of room temperature fluid is injected as a bolus into the proximal (right atrium) lumen of the PAC, and the resulting change in the pulmonary artery blood temperature is recorded by the thermistor at the catheter tip. In adults, an injectate volume of 10 mL should be used, while in children, an injectate volume of 0.15 mL/kg is recommended.[345] As in all other forms of cardiovascular monitoring, it is important to have a real-time display of the thermodilution curve resulting from each cardiac output measurement.[345] This allows the clinician to discern artifacts that would invalidate the cardiac output measurement, such as unstable blood temperature, recirculation, or incomplete indicator injection.

Usually three cardiac output measurements performed in rapid succession are averaged to provide a more reliable result. If only a single injection is used to determine cardiac output, a difference between sequential cardiac output measurements of 22% is required to suggest a clinically significant change. In contrast, when three injections are

BOX 36.8 Factors Influencing Accuracy of Thermodilution Cardiac Output Measurement

- Intracardiac shunts
- Tricuspid or pulmonic valve regurgitation
- Inadequate delivery of thermal indicator
  - Central venous injection site within catheter introducer sheath
  - Warming of iced injectate
- Thermistor malfunction from fibrin or clot
- Pulmonary artery blood temperature fluctuations
  - Following cardiopulmonary bypass
  - Rapid intravenous fluid administration
- Respiratory cycle influences

averaged to determine the thermodilution measurement, a change greater than 13% indicates a clinically significant change in cardiac output.[346]

Even when carefully performed, some studies have found that thermodilution cardiac output measurements may not agree with other reference methods.[347,348] However, few complications are directly attributable to the technique itself, and following the trend in cardiac output is probably more clinically useful than emphasizing any absolute value.

Sources of Error in Thermodilution Cardiac Output Monitoring

Several important technical issues and potential sources of error must be considered to interpret thermodilution cardiac output measurements properly (Box 36.8).[344,345] The thermodilution technique measures RV output. With **intracardiac shunt**, RV and LV outputs will not be equal.

Patients with **tricuspid or pulmonic valve regurgitation** pose additional problems for thermodilution cardiac output measurement owing to recirculation of the indicator across the incompetent valve. Although minor degrees of valvular regurgitation have little effect on thermodilution cardiac output monitoring, these values are unreliable with more severe valvular regurgitation, either underestimated or overestimated, depending on the severity of valvular regurgitation and the magnitude of the cardiac output.[345,349]

Unrecognized **fluctuation in blood temperature** may also influence cardiac output measurement. In most patients, pulmonary artery blood temperature falls somewhat in the initial minutes **following cardiopulmonary bypass,** when the rewarmed vascular and vessel rich tissues redistribute the heat gained to the less well perfused body core. Therefore, the thermal baseline is unstable and measurements made in the minutes following bypass are notoriously unreliable, most often leading to marked underestimation of the true cardiac output.[350] Pulmonary artery blood temperature can also change due to **rapid fluid infusion.**[351]

One controversy surrounding bolus thermodilution cardiac output monitoring is the proper timing of measurement in relation to the **respiratory cycle**, particularly in patients receiving positive pressure mechanical ventilation, because RV stroke output varies as much as 50% during the respiratory cycle. Although reproducibility of consecutive measurements improves markedly when the bolus injections are synchronized to the same phase of the respiratory cycle, an accurate measurement of average cardiac output is achieved more reliably by making multiple injections during the different phases of the respiratory cycle and then averaging the results.[345,352]

Last, the measured thermodilution cardiac output can overestimate true cardiac output during low flow states because of significant heat loss from slow injectate transit.[353]

Continuous Thermodilution Cardiac Output Monitoring

Newer technologies applied to PAC monitoring allow nearly continuous cardiac output monitoring using warm thermal indicator.[344,354] In brief, small quantities of heat are released from a 10-cm thermal filament incorporated into the RV portion of a PAC, approximately 15 to 25 cm from the catheter tip, and the resulting thermal signal is measured by the thermistor at the tip of the catheter in the pulmonary artery. The heating filament is cycled on and off in a pseudorandom binary sequence, and the cardiac output is derived from cross correlation of the measured pulmonary artery temperature with the known sequence of heating filament activation.[354] Typically, the displayed value for cardiac output is updated every 30 to 60 seconds and represents the average value for the cardiac output measured over the previous 3 to 6 minutes. On the one hand, this will lead to a delayed response during unstable hemodynamic conditions.[355] On the other hand, reproducibility and precision appear to be better compared with the single instantaneous bolus thermodilution technique, especially during positive pressure ventilation.[356,357]

The CCO PAC has been widely accepted into clinical use for a number of practical reasons. Although these catheters are more expensive than standard PACs, obviating the need for bolus injections reduces nursing workload and the potential risk of fluid overload or infection. However, like cold bolus thermodilution techniques, warm thermal CCO has certain methodological pitfalls that must be recognized and avoided. The CCO computer and catheter require a significant amount of time to warm up and may work poorly in an environment where there is a great deal of thermal noise, such as the cardiac operating room. Recent observations also suggest that the use of pneumatic compression devices may introduce artifacts that appear as large variations (oscillations) in CCO values in otherwise stable patients.[358] As already emphasized, CCO monitors have an inherent 5- to 15-minute delay in responding to abrupt changes in cardiac output, and the magnitude of this delay depends on the type of physiologic perturbation, as well as the CCO computer monitor algorithm.[355] Although modifications of CCO algorithms provide a “STAT Mode” rapid response time, acute changes in cardiac output are still detected more slowly by CCO monitoring than by other methods, such as direct arterial pressure or mixed venous oximetry. In effect, the CCO technique involves a fundamental tradeoff between rapid response time and overall accuracy and stability of the displayed value.[356] While it might be useful for clinical decision making, no studies exist that demonstrate improved patient outcomes from use of the CCO PAC.

Transpulmonary Thermodilution Cardiac Output

For transpulmonary thermodilution measurement, ice-cold saline is injected into a central venous line while the change in temperature is measured in a large peripheral artery (femoral, axillary, or brachial artery) via a special arterial catheter equipped with a thermistor.[359] Several studies have shown adequate agreement with standard thermodilution cardiac output.[360,361] In contrast to the standard thermodilution method, the transpulmonary thermodilution measurement lasts over several respiratory cycles and thereby obviates the respiratory effects on stroke volume and measured cardiac output.[362]

Mathematical derivation from the transpulmonary thermodilution curve can produce several additional useful indices. Extravascular lung water is a measure of pulmonary edema and can be used to guide fluid therapy in patients with acute lung injury or sepsis.[363-365] Other derived indices are the global end-diastolic volume and intrathoracic blood volume. Several studies have found these indices to be a better measure of cardiac preload than traditional measurements such as CVP or PAWP.[366,367] However, it appears that these indices still cannot predict cardiac output response to fluid loading.[368] Another parameter derived from the transpulmonary thermodilution curve is the cardiac function index, calculated using cardiac output and the intrathoracic blood volume. In patients without RV failure, it has been shown to correlate with LV ejection fraction and its response to inotropic therapy.[369]

LITHIUM DILUTION CARDIAC OUTPUT MONITORING

The lithium dilution technique is another cardiac output monitoring method that derives its fundamental basis from indicator dilution principles.[370] In brief, following an intravenous bolus injection of a small dose of lithium chloride, an ion-selective electrode attached to a peripheral arterial catheter measures the lithium dilution curve, from which the cardiac output is derived. Several studies have shown that this is an accurate technique compared with standard thermodilution or electromagnetic flowmetry.[371,372] The lithium indicator can be injected through a peripheral intravenous catheter with similar measurement accuracy, thus eliminating the need for a central venous line.[373] This technique can also be used in children.[374] Lithium dilution cannot be used in patients who are taking lithium or those who have just received nondepolarizing neuromuscular blockers, since the latter also alter the lithium sensor electrode measurement.

OTHER METHODS FOR MONITORING CARDIAC OUTPUT AND PERFUSION

In recent years, much work has been dedicated to developing minimal or non-invasive methods to measure cardiac output. While it seems that these methods' overall agreement with the traditional thermodilution method is not very high,[375] they do offer other advantages. Some of these newer methods are discussed herein.

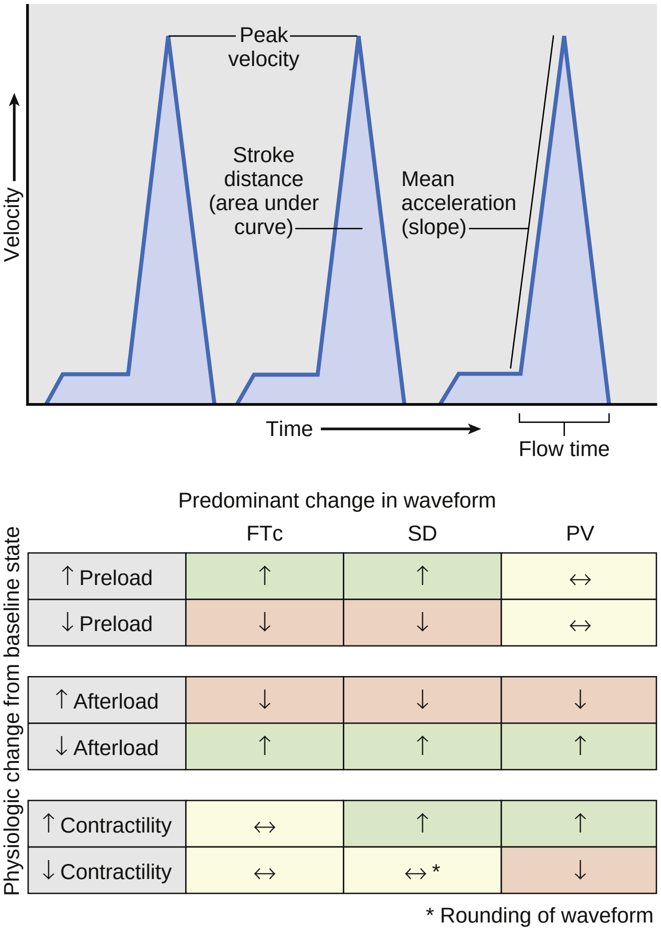
Esophageal Doppler Cardiac Output Monitoring

All of the ultrasound-based methods for cardiac output monitoring employ the Doppler principle as described in detail in Chapter 37. While cardiac output can be intermittently measured by the Doppler technique during transthoracic or transesophageal echocardiography examinations, for monitoring purposes, a special esophageal Doppler probe has been developed that allows continuous monitoring of cardiac output by measuring the Doppler shift of the interrogated blood flow in the descending thoracic aorta. The Doppler probe is inserted into the esophagus to a depth of approximately 35 cm from the incisor teeth and is adjusted to optimize the audible Doppler flow sound from the descending aorta, which lies in close proximity and runs essentially parallel to the esophagus at this location.[376]

Several limitations of the esophageal Doppler technique must be appreciated by the physician to avoid pitfalls in data interpretation. This monitoring method interrogates blood flow in the descending thoracic aorta and therefore only measures a fraction of total cardiac output. To report total cardiac output, either the esophageal Doppler measurement must be "calibrated" by some alternative method, or an empirically determined correction constant of 1.4 is used.[376] This constant is accurate for most patients but does not apply universally, especially in the presence of conditions that redistribute blood flow, such as pregnancy, aortic cross-clamping, and following cardiopulmonary bypass.[377,378] In addition, the descending thoracic aorta diameter is either measured using A-mode ultrasound or calculated from a nomogram based on the patient's age, sex, height, and weight.[376] When calculated, it is assumed that the aortic diameter does not change throughout the cardiac cycle. In addition to these considerations, the technique is likely to be inaccurate in the presence of aortic valve stenosis or regurgitation, or in patients with thoracic aortic disease. It is not easily applied in nontracheally intubated non-sedated patients, and it cannot be used in individuals with esophageal pathology. Finally, like all ultrasound techniques, the acoustic window needed to acquire the Doppler signal may not be adequate in some individuals, thereby precluding use of this method.

Advantages of the esophageal Doppler monitoring technique include its ease of use, minimal invasiveness, and inherent safety. It appears that limited experience is needed for clinical success—as few as 10 to 12 cases for accurate application of the technique.[377] A review of 25 clinical trials comparing esophageal Doppler cardiac output measurement with PAC thermodilution measurements noted that the Doppler cardiac output values correlated well with thermodilution measurements and showed minimal overall bias and good tracking of directional changes in thermodilution cardiac output with low intra- and inter-observer measurement variability.[377]

Recently, the esophageal Doppler method has seen renewed popularity.[379,380] Current devices provide a clear visual display of the spectral Doppler waveform and also calculate and display additional hemodynamic variables including the peak blood flow velocity, flow acceleration, and heart rate-corrected flow time (Fig. 36.51). Some studies have shown that these additional measures provide useful information about LV preload, fluid responsiveness, contractility, and systemic vascular resistance.[381-383] Additionally, respiratory variability of the aortic blood flow velocity can be used to predict cardiac output response to a fluid bolus.[384] One of the more important benefits of this monitor may be focusing clinical attention on optimizing



Peak velocity
Stroke distance (area under curve)
Mean acceleration (slope)
Velocity
Time
Flow time
Predominant change in waveform
Physiologic change from baseline state

	FTc	SD	PV
↑ Preload	↑	↑	↔
↓ Preload	↓	↓	↔
↑ Afterload	↓	↓	↓

↑ Contractility	↔	↑	↑
↓ Contractility	↔	↔ *	↓

* Rounding of waveform

Fig. 36.51 The velocity-time waveform displayed by esophageal Doppler cardiac output monitoring devices reflects alterations in contractility, preload, and afterload. Stroke distance *(SD)* is directly related to calculated stroke volume and provides a useful surrogate measure of cardiac output. *FTc*, Systolic flow time corrected for heart rate; *PV*, peak velocity.

stroke volume rather than total cardiac output. Indeed, in critically ill patients, complications may be better predicted by low stroke volume than by low cardiac output.[385] Several studies have shown that hemodynamic optimization, guided by maximizing esophageal Doppler-measured stroke volume in moderate-risk surgical patients, reduces perioperative morbidity and shortens hospital stay.[379,380,386]

Bioimpedance and Bioreactance Cardiac Output Monitoring

The technique of bioimpedance cardiac output monitoring was first described by Kubicek and associates and is based on changes in electrical impedance of the thoracic cavity or the whole body occurring with ejection of blood during cardiac systole.[387] As blood has a significantly lower electrical resistance compared with tissues, changes in impedance to electrical flow reflect a change in blood volume, and this can be used to calculate stroke volume.[388]

For bioimpedance measurement, disposable electrodes are applied to the skin surface along the sides of the neck and lateral aspect of the costal margin (thoracic bioimpedance) or to the four limbs (whole body bioimpedance); a high-frequency, low-amplitude electrical current is applied; and the voltage change is measured. Patient height, weight, and gender are used to calculate the volume of the thoracic cavity. Bioimpedance cardiac output is computed for each cardiac cycle and continuously displayed as an average value over several heart beats.

Although many studies suggest that the bioimpedance method is accurate in healthy volunteers, its reliability deteriorates in surgical and critically ill patients.[389] This led to attempts at improving the technology used. A newer technique, termed bioreactance cardiac output monitoring, measures not only the amplitude change of the received signal, but also its phase shift compared to the applied electrical signal. It utilizes four dual-electrode patches, placed two on each side of the body.[388] Compared to the standard bioimpedance method, the bioreactance method shows somewhat better agreement with traditional cardiac output calculations. Several clinical scenarios where this new method has been validated include the prediction of fluid responsiveness when using the passive leg raising test in patients after cardiac surgery and evaluating cardiac output change during exercise stress testing.[388]

Partial CO_2 Rebreathing Cardiac Output Monitoring

Another method for cardiac output monitoring that does not require a PAC is the partial CO_2 rebreathing technique.[390,391] Owing to the difficulty encountered in the standard Fick method involving measuring oxygen consumption and mixed venous hemoglobin saturation, this alternative technique is based upon a restatement of the Fick Equation for carbon dioxide elimination rather than oxygen uptake.

$$\dot{Q} = \frac{\dot{V}CO_2}{(C_{\dot{v}}CO_2 - C_aCO_2)} \qquad (36.3)$$

Where,

$\dot{Q}$ = cardiac output
$\dot{V}CO_2$ = rate of carbon dioxide elimination
$C_{\dot{v}}CO_2$ = carbon dioxide content of mixed venous blood
C_aCO_2 = carbon dioxide content of arterial blood

This method uses the change in CO_2 production and end-tidal CO_2 concentration in response to a brief, sudden change in minute ventilation. With a specifically designed breathing system and monitoring computer, this measurement is easily performed in any tracheally intubated patient. Changes in end-tidal CO_2 in response to the rebreathing maneuver are used to calculate cardiac output by a differential version of the Fick equation for carbon dioxide. The attractive features of this method are that it is entirely noninvasive, it can be performed every few minutes, and the brief episodes of rebreathing pose no substantial risk to most patients, with end-tidal CO_2 measurements increasing by less than 3 mm Hg. However, as currently designed, accurate measurements with this technique require tracheal intubation for precise measurement of exhaled gasses. Furthermore, changing patterns of ventilation may have an unpredictable influence on the measurement. As with all Fick-based techniques, the partial CO_2 rebreathing method measures pulmonary capillary blood flow as an indicator of total cardiac output and thus requires correction for pulmonary shunt.

Initial clinical trials suggested reasonably good agreement between the partial rebreathing CO_2 cardiac output method and other techniques, such as thermodilution. However, as with most of these alternative monitoring methods, the clinical trials are small and mainly focused on specific patient groups, particularly coronary artery bypass surgery patients.[392] At present, the clinical role for this technique is mainly focused on short-term intraoperative applications or mechanically ventilated postoperative patients. Due to the mandatory increase in arterial pCO_2, the technique is relatively contraindicated in patients with increased intracranial pressure.

Pulse Contour Cardiac Output Monitoring

Much of recent development in the area of cardiac output monitoring has been focused on continuous measurement of cardiac output derived from the analysis of the arterial pulse pressure waveform. These methods, generally termed pulse contour cardiac output, determine stroke volume from computerized analysis of the area under the arterial pressure waveform recorded from an arterial catheter or even a noninvasive finger blood pressure waveform.[393-396] Pulse contour methods offer the potential for non-invasive, continuous, beat-to-beat cardiac output monitoring. Also, the change in stroke volume from beat to beat (termed SVV) in response to tidal ventilation can be used to evaluate volume status in ventilated patients.[147,397]

However, several shortcomings need to be considered.[398,399] First, a baseline calibration with a known cardiac output is required to account for individual differences in vascular resistance, impedance, and wave reflectance. Additionally, recalibration is required every 8 to 12 hours to account for changes in vascular characteristics over time. Also, the use of vasopressors might affect the accuracy of pulse contour methods.[400] This need for external calibration might require the use of a more invasive technique, negating the non-invasiveness advantage of pulse contour methods. Recently, several systems were developed with the capability for an auto-calibration based on a patient's demographic variables. However, the accuracy of this auto-calibration in various clinical situations is questionable.[401] A reasonably well-defined arterial pressure waveform with a discernible dicrotic notch is required for accurate identification of systole and diastole, a condition that might not exist under severe tachycardia or dysrhythmia, or other very low-output states. Last, for a meaningful use of beat-to-beat variation in stroke volume (as well as systolic pressure or PPV), the patient needs to be on controlled mechanical ventilation with a tidal volume of at least 8 mL/kg body weight and to be in a regular cardiac rhythm.[402]

Notwithstanding these shortcomings, clinical trials in surgical patients have shown that the pulse contour cardiac output methods provide an acceptable level of accuracy with a bias of less than 0.5 L/min compared to thermodilution cardiac output.[395,403,404] SVV above 10% has been shown to be a useful predictor of fluid responsiveness.[138] Last, several recent studies have shown that goal-directed therapy based on either maximizing pulse contour derived cardiac output or minimizing SVV results in improved perioperative outcomes.[405-407]

Acknowledgment

This chapter is a consolidation of two chapters in the eighth edition, Chapter 45 Cardiovascular Monitoring and Chapter 47 Electrocardiography, Perioperative Ischemia, and Myocardial Infarction. The editors and publisher would like to thank the following authors: Shahar Bar-Yosef, Giora Landesberg, and Zak Hillel for their contributions to the prior edition of this work. Their contributions have served as the foundation for the current chapter.

Perioperative Echocardiography

MEGAN L. KRAJEWSKI and FEROZE MAHMOOD

KEY POINTS

- Perioperative applications of transesophageal echocardiography (TEE) include monitoring, diagnosis, and procedural guidance. The role of TEE in cardiac surgery, noncardiac surgery, interventional procedures, and critical care continues to evolve.
- In noncardiac surgery, intraoperative TEE serves as a routine monitor or as a rescue tool in life-threatening emergencies.
- TEE aids in decision making during cardiac surgery, and three-dimensional (3-D) TEE adds incremental value in intraoperative assessments.
- TEE is integral to structural heart interventions and is a key component of multimodality imaging.
- Echocardiography plays a vital role in the diagnosis and management of shock.
- Applications of transthoracic echocardiography (TTE) in the perioperative setting are expanding.
- Focused cardiac ultrasound is performed and interpreted at the point of care, and addresses specific questions relevant to the clinical context.
- Critical care societies have proposed distinct competencies and guidelines for critical care echocardiography beyond those included in perioperative TEE guidelines. The skill set of the intensivist performing echocardiography overlaps with that of the intraoperative echocardiographer and includes other unique components.
- Basic knowledge of echocardiography is an expectation of anesthesiology training.
- Simulation is an effective training tool when integrated within a multimodal, curriculum-based approach to echocardiography education.

Introduction

Echocardiography is an invaluable tool used throughout the perioperative period. Image acquisition and interpretation occur at the point of care, enabling real-time integration of the findings in the context of the patient's clinical condition. Transesophageal echocardiography (TEE) has broad functionality in the perioperative environment. TEE serves as an intraoperative monitor, provides detailed structural and functional information, facilitates diagnosis of pathology, and guides percutaneous interventions. Applications of TEE have expanded within cardiac surgery, and into the realms of noncardiac surgery, catheter-based procedures, and critical care. As the use of clinical ultrasound grows in modern anesthetic practice, perioperative clinicians are also beginning to embrace transthoracic echocardiography (TTE). Critical care echocardiography shares many similarities with intraoperative echocardiography, but is simultaneously evolving under the larger umbrella of critical care ultrasonography. This chapter provides a historical synopsis and summary of imaging techniques and echocardiographic views and discusses applications of TEE and TTE in perioperative care.

History of Perioperative Echocardiography

INTRAOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Decades of evolution and advancement have led to the current state of perioperative TEE (Fig. 37.1).[1] Clinical echocardiography first emerged in the 1950s with the use of motion mode (M-mode) ultrasound to record signals from cardiac structures.[2] Nearly two decades later, the first intraoperative echocardiography was performed with epicardial imaging.[3] The first practical clinical application of TEE was reported in 1976.[4] Soon after, a group reported the first use of intraoperative TEE[5] and described its utility in monitoring left ventricular (LV) function during cardiac surgery.[6] In the 1980s, the mounting of two-dimensional (2-D) transducers onto modified flexible gastroscopes[7,8] created more versatile probes, and pioneering anesthesiologists and cardiologists began to demonstrate the usefulness of TEE as an intraoperative monitor.[9-11] Further advancements such as transducers with combined 2-D and Doppler capabilities,[12,13] biplane imaging,[14] multiplane imaging,[15] and pediatric probes[16] unlocked the diagnostic potential of intraoperative TEE. Real-time three-dimensional imaging (RT-3D) entered the scene in the mid-2000s,[17] and since then its intraoperative use has grown exponentially. Advances in probe technology and improved computing power continue to further the practicality of three-dimensional (3-D) image acquisition.

CRITICAL CARE ECHOCARDIOGRAPHY

Prior to the introduction of TEE in 1976, significant advances in 2-D transthoracic imaging occurred, leading to better visualization of cardiac structures.[18-22] Production of commercially available instruments soon followed. In the intensive care units (ICUs), some clinicians incorporated echocardiography in the evaluation of cardiac function in acute respiratory distress syndrome and sepsis.[23,24]

TTE was not widely disseminated in ICUs, however, as the intensivist's tool of choice at the time was the pulmonary artery catheter.[25-27] During the late 1990s to 2000s, the use of pulmonary artery catheters declined,[28-32] and TTE simultaneously gained more traction in the ICUs. With the miniaturization of equipment and emphasis on point-of-care ultrasound, use of echocardiography as a hemodynamic monitor and diagnostic tool in the ICU continues to increase.

Principles of Ultrasound

While a thorough discussion of ultrasound physics is beyond the scope of this chapter, a basic understanding of fundamental concepts is requisite for any echocardiographer. Sound is a mechanical, longitudinal wave of vibrations propagated through a medium. Several parameters describe sound waves including frequency, wavelength, amplitude, and propagation speed. Ultrasound waves are sound waves with frequencies above the audible human range (20-20,000 hertz [Hz]). Echocardiography typically uses frequencies between 2 and 12 megahertz (MHz). Ultrasound transducers use piezoelectric elements to convert ultrasound energy into electrical energy and vice versa. Transducers function both as transmitters and receivers of ultrasound signals. 2-D echocardiography uses a phased-array transducer, which has a row of electrically interconnected piezoelectric elements.

As ultrasound energy propagates through tissue, interactions between the wave and tissue result in absorption, divergence, reflection, and scattering of the energy. Reflection of ultrasound energy at tissue interfaces forms the basis of image generation. These sound-tissue interactions reduce the intensity of the ultrasound signal, and this attenuation limits the depth of imaging. Transmitted energy at tissue interfaces often undergoes refraction and changes directions, contributing to imaging artifacts.

The accurate display of an image depends on imaging resolution, components of which include spatial resolution, temporal resolution, and contrast resolution (Table 37.1). Spatial resolution can be described according to the three beam dimensions: axial, lateral, and elevational. Image formation involves a tradeoff between spatial resolution and depth of penetration. Higher frequency (shorter wavelength) transducers provide superior axial resolution, but limited penetration depth due to attenuation. Lower frequencies (longer wavelengths) penetrate more deeply at the expense of axial resolution. Higher

TABLE 37.1 Components of Imaging Resolution

	Description	Practical points
Spatial resolution	The ability to discriminate between two closely-spaced objects The minimum distance necessary between two structures so that they are displayed as separate objects	Determines image details Factors that improve spatial resolution often come at the expense of decreased temporal resolution and vice versa
Axial	Differentiates between objects along the length of the ultrasound beam	Higher frequency transducers have shorter wavelengths and better axial resolution Axial resolution is superior to lateral resolution
Lateral	Discriminates side-to-side (or horizontal) relative to the direction of the beam	Determined by the beam width Best at the focal point of the beam
Elevational	Discriminates between objects vertical to the plane of the ultrasound beam	Determined by the beam height Best at the focal point of the beam
Temporal resolution	The ability to accurately display a structure's motion with respect to time	The higher the frame rate, the better the temporal resolution Factors that decrease the time to scan the sector (e.g., decreasing the imaging depth or creating a narrower imaging sector) improve temporal resolution
Contrast resolution	The ability to resolve subtle differences in echogenicity, which are displayed as different shades of gray	Improved by harmonic imaging, use of contrast agents, B-color maps, and post-processing controls

frequencies are better for imaging superficial structures; lower frequencies are better for deeper structures.

Formation of ultrasound images relies on several assumptions: (1) ultrasound energy propagates in a straight line; (2) all returning echoes originate from the central beam, which is extremely thin; (3) echoes return to the transducer after one reflection; (4) attenuation is constant; and (5) the speed of sound is constant, therefore the depth of a reflector is proportional to the round-trip transit time.[33] Violations of these assumptions result in imaging artifacts. Spectral and color flow Doppler (CFD) and 3-D images are also susceptible to imaging artifacts.

Ultrasound Modalities

Key ultrasound modalities used in echocardiography include motion mode (M-mode), 2-D imaging, Doppler (spectral and color flow), and Doppler tissue imaging (DTI). Table 37.2 highlights important aspects of these techniques. Additional techniques may be applied in specific contexts and are introduced in the next section.

STRAIN AND STRAIN-RATE IMAGING

Strain and strain-rate imaging techniques (also called cardiac mechanics or myocardial deformation) are used to quantify global and regional ventricular function. Strain is the relative change in shape or size of an object as a result of an applied force. In the context of the myocardium, it is the fractional change in the length of a segment relative to its baseline and expressed as a percentage. Positive strain indicates lengthening or thickening and negative strain represents shortening or thinning. Three axes are relevant to myocardial deformation: longitudinal, circumferential, and radial. Normal deformation patterns during systole are longitudinal shortening (negative strain), circumferential shortening (negative strain), and radial thickening (positive strain).

Methods for strain analysis include DTI and the more commonly used speckle tracking echocardiography (STE). DTI measures velocities at two points in the myocardium and derives the strain and strain rate. STE, in contrast, tracks unique acoustic speckles in the myocardium over a series of frames and derives strain and strain rate from the change in distance. Duncan and colleagues have written an excellent review on perioperative strain and strain-rate imaging.[34]

HARMONIC IMAGING

Harmonic imaging is a processing technique used to improve the quality of 2-D images.[35] A sound wave propagates nonlinearly through tissue, distorting the wave's shape. This produces harmonic frequencies, which are integer multiples of the fundamental frequency originally transmitted by transducer. Signals return to the transducer at both the fundamental frequency and harmonic frequencies. Harmonic imaging typically creates images from the second harmonic frequency and filters the fundamental frequency signals. Harmonic imaging increases contrast resolution, improves signal-to-noise ratio, and decreases some artifacts. Disadvantages include slightly decreased spatial resolution and thickened appearance of some cardiac structures.[36,37]

CONTRAST ECHOCARDIOGRAPHY

Contrast echocardiography can be used to improve diagnostic evaluation and enhance suboptimal images.[38,39] Two methods of contrast echocardiography include injection of agitated saline or injection of commercially available contrast agents. Agitated saline can be used to identify the presence of intracardiac right-to-left shunt, because microbubbles created by agitation do not cross the pulmonary circulation.[40] Commercially available contrast agents use encapsulated microbubbles of high-density gas and are able to traverse the pulmonary circulation, allowing for opacification of the left side of the heart. Perioperative applications

TABLE 37.2 Ultrasound Modalities

Modality	Description/Features
Brightness Mode (B-mode)	■ Depicts the strength of returning sound signals using corresponding degrees of brightness ■ M-mode and 2D imaging are modifications of original B-mode imaging
Motion Mode (M-mode)	■ Displays a one-dimensional image of the motion of cardiac structures relative to time ■ Very high temporal resolution ■ Provides limited spatial information ■ Greatest utility in providing information about rapidly moving structures (e.g., valves, walls) in relation to the timing of the cardiac cycle
Two-Dimensional (2D)	■ The mainstay of the echocardiographic examination ■ Scanning of repeated pulses generates an image representative of the cardiac structures with real-time motion ■ Images are produced in a sector format ■ Temporal resolution is less than that of M-mode
Doppler	■ Ultrasound energy scattered from moving red blood cells shifts to a higher frequency when moving toward the transducer and a lower frequency when moving away ■ Doppler modes analyze this frequency shift and use the Doppler equation to estimate velocities of blood flow ■ Velocity (*v*) can be calculated as follows: $v = \frac{c * \Delta f}{2 f_t * cos\theta}$ Where c = the propagation speed of sound in blood (1540 m/s), Δf is the difference between the transmitted frequency (f_t) and the received frequency, and $\cos\theta$ is the angle of incidence between the ultrasound beam and blood flow ■ Angle-dependent ■ Maximum Doppler shift occurs when blood flow is directly parallel to the beam. When the incident angle is ≤ 20 degrees, the percentage error in estimating the velocity is ≤ 6%. At greater incident angles the error significantly increases. ■ Includes spectral (pulsed-wave, continuous wave) and color flow Doppler
Pulsed-Wave Doppler (PWD)	■ Samples blood flow velocities at a specific location ■ The frequency of sampling determines the maximum velocity that can be detected and depends on imaging depth ■ This maximum velocity is half of the pulse repetition frequency and referred to as the Nyquist limit ■ Above the Nyquist limit, *aliasing* occurs. The Doppler information is displayed ambiguously, displaying both positive and negative velocities
Continuous Wave Doppler (CWD)	■ Transducer continuously transmits and receives ultrasound energy along the length of the ultrasound beam ■ Allows measurement of higher velocity flows, such as those that are encountered with stenotic or regurgitant lesions ■ The location of the high velocity flow may occur anywhere along the length of the beam, a limitation referred to as *range ambiguity*
Color Flow Doppler (CFD)	■ A form of pulsed-wave Doppler ■ The direction and velocity of flow are measured in multiple sample volumes within an imaging sector. The direction and velocity information are displayed according to a color scale ■ Flow data are superimposed on the corresponding 2D image ■ Limited by aliasing ■ Lower temporal resolution than 2D imaging
Doppler Tissue Imaging (DTI)	■ Used to assess myocardial motion ■ Eliminates the high-velocity, low-amplitude signals from red blood cells and displays the low-velocity, high-amplitude signals from tissue ■ Angle-dependent ■ Does not distinguish between translational motion and contraction

of contrast echocardiography include improved endocardial border delineation for assessment of function, assessment of regional wall motion, and exclusion of intracardiac thrombus or mass.

Three-Dimensional Image Acquisition

3-D imaging provides information that complements the findings from the 2-D examination. Transducers with 3-D capabilities contain thousands of piezoelectric elements in a rectangular (or matrix) array configuration and create pyramidal-shaped images. The optimal 3-D image involves tradeoffs between temporal resolution, spatial resolution, and sector size. 3-D imaging is susceptible to the same artifacts as 2-D imaging and additional artifacts unique to 3-D image construction. We encourage the interested reader to refer to published 3-D echocardiography guidelines[41] as well as a practical overview focused on intraoperative 3-D image acquisition.[42]

IMAGING MODES

Two-Dimensional Multiplane Acquisition

Matrix array (3-D) transducers have multiplane imaging capabilities and can simultaneously display two or

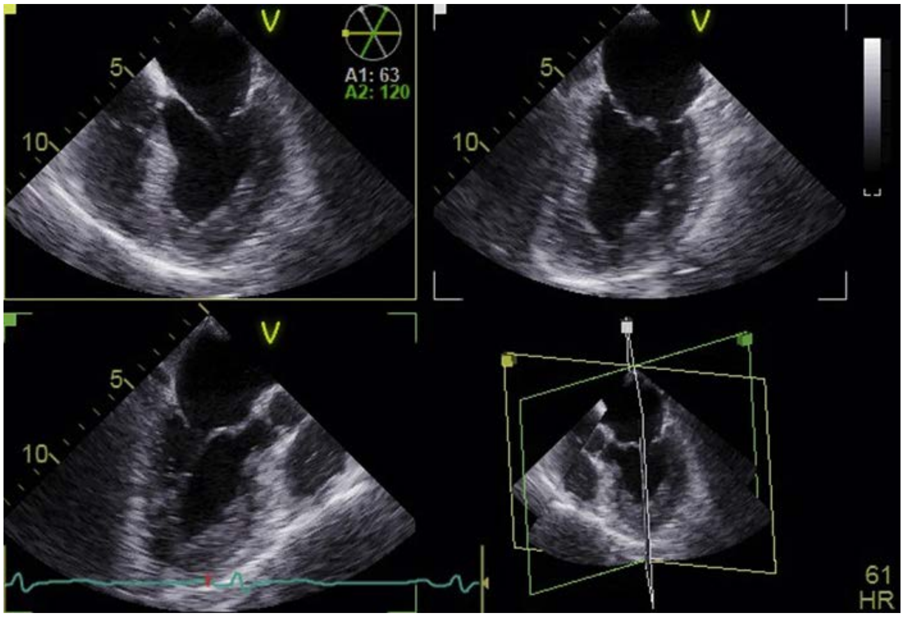

Fig. 37.2 Simultaneous display of multiple two-dimensional scan planes by multiplane imaging. The upper left panel *(yellow panel)* displays the primary reference imaging plane. The circular icon in this panel indicates the positions of the secondary imaging planes. Images from the secondary planes are displayed at the top right *(white panel)* and bottom left *(green panel)*. A three-dimensional representation of the imaging planes and their angulation is displayed at the bottom right.

BOX 37.1 **Perioperative Applications of Multiplane Imaging**

- Simultaneous visualization of segmental wall motion
- Characterization of the mechanism and origin of valvular regurgitation
- Procedural guidance during percutaneous closure of atrial septal defect
- Guidance of transseptal puncture for transcatheter left atrial appendage and mitral valve procedures
- Evaluation of the left atrial appendage morphology and exclusion of thrombus

more live 2-D imaging planes. In biplane imaging, the first image serves as the reference view, and the second image is obtained by rotating the scanning plane around the longitudinal axis of the reference view. The secondary image can also be adjusted by tilting the imaging plane in the elevational or lateral axis. Multiplane imaging allows simultaneous display of multiple rotatable imaging planes (Fig. 37.2). Box 37.1 lists common perioperative applications of multiplane imaging.

Real-Time Three-Dimensional Imaging

3-D images can be displayed live or in “real time.” RT-3D imaging acquires data over a single heartbeat; some authors refer to this as 4-D imaging. The proprietary nomenclature varies, but there are three main RT-3D modes of differing sector size:

- Narrow sector: this mode displays a pyramidal volume with the best temporal and spatial resolution of the live modes. The major limitation is that it often does not capture an entire structure of interest (Fig. 37.3).
- Wide sector: this mode “zooms in” on a selected region of interest. There is a decrease in temporal and spatial resolution compared to narrow sector imaging. Images are easy to acquire. This mode is ideal for real-time image manipulation (see Fig. 37.3).
- Full-volume: full-volume mode has the largest imaging sector. Live full-volume images have reduced temporal and spatial resolution. Ideally, acquisition of full-volume images occurs over multiple beats. Live full-volume mode has utility when multiple-beat acquisition is not feasible.

Gated Acquisition

Gated acquisition divides the imaging volume into multiple narrow subvolumes that are acquired over a specified number of heartbeats. “Stitching” the subvolumes together creates the final image. In order to obtain the subvolumes at the same time in the cardiac cycle, image acquisition is gated to the R-wave of the electrocardiogram (ECG). Gated acquisition requires normal cardiac rhythm and the absence of electrical interference and respiratory variation.

- Wide sector: multiple-beat gated acquisition using wide sector mode significantly improves the temporal resolution of the “zoomed in” view. Spatial resolution marginally improves.
- Full-volume: this mode has the largest sector size with optimal spatial resolution and high temporal resolution (Fig. 37.4; Video 37.1).

Color Flow Doppler

CFD may be incorporated with any of the modalities, but leads to a reduction in temporal resolution. Optimal CFD images are obtained using R-wave gated multiple beat acquisitions.

QUANTITATIVE ANALYSIS

Multiplanar Reformatting

Multiplanar reformatting enables alignment of orthogonal planes to accurately measure linear dimensions and areas (e.g., planimetry of stenotic orifice, annular area).

In this example, subvolume acquisition occurs over five consecutive heartbeats. The individual subvolumes are then synchronized and "stitched" together to create a larger full-volume three-dimensional image. (B) Creation of the three-dimensional (3D) full-volume image from narrow subvolumes. (Modified from Desjardins G. Perioperative echocardiography. In: Miller R, ed. *Miller's Anesthesia*. 8th ed. Philadelphia, PA: Elsevier/Saunders; 2015:1396–1428.)

Advanced Applications

Quantitative applications exist for 3-D imaging and eliminate some of the geometric assumptions required in 2-D imaging calculations. Example analyses include calculation of ventricular ejection fraction (EF), analysis of mitral valve structure, and dynamic annular measurements. The degree of automation and need for post-processing manipulation vary. Some analyses are performed exclusively offline, making them useful in research, but less applicable to intraoperative decision making.

Indications and Practice Guidelines

PERIOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY

The American Society of Anesthesiology (ASA) and Society of Cardiovascular Anesthesiologists (SCA) issued perioperative TEE practice guidelines in 1996, categorizing indications for TEE in various clinical settings.[43] An updated version in 2010 recommended the indications for perioperative TEE based on literature review and expert opinion.[44] In the absence of contraindications, TEE should be used in all adult open heart and thoracic aortic surgical procedures. It should be considered in coronary artery bypass graft surgeries to confirm diagnostic information, detect pathology, influence the anesthetic or surgical plan, and assess surgical results. It is recommended that TEE be considered on a case-by-case basis in small children undergoing cardiac surgery due to unique risks in this population. For catheter-based intracardiac procedures, the 2010 guidelines state TEE may be used. Separate guidelines focus specifically on the role of echocardiography in interventional and catheter-based procedures.[45,46] In noncardiac surgery, TEE is indicated in the setting of persistent unexplained life-threatening circulatory instability. If the surgical procedure or the patient's known or suspected pathology could result in severe hemodynamic, pulmonary, or neurologic compromise, TEE may be used. TEE is recommended in critical care if the diagnostic information is expected to alter management and cannot be obtained by other modalities expediently. European guidelines offer similar recommendations for the use of perioperative TEE,[47-49] while the American Heart Association (AHA) and American College of Cardiology (ACC) make more limited recommendations regarding specific indications for intraoperative TEE.[50,51]

In addition to describing indications for perioperative TEE, the 1996 ASA/SCA guidelines also distinguish between basic and advanced levels of training.[43] In 2002, an American Society of Echocardiography (ASE)/SCA Joint Task Force authored guidelines for training in perioperative echocardiography, defined as TEE, epicardial echocardiography, or epiaortic ultrasonography performed in surgical patients immediately before, during, or after surgery.[52] These guidelines do not include TTE. Expectations for cognitive and technical skills of both basic and advanced training are outlined with recommendations for the minimum numbers of echocardiographic examinations performed. Further discussion of training and certification occurs at the end of the chapter.

TABLE 37.3 List of Contraindications to Transesophageal Echocardiography

Absolute Contraindications	Relative Contraindications
Esophageal pathology ■ Diverticulum ■ Laceration ■ Stricture ■ Tumor	History of: ■ Dysphagia ■ Radiation to neck and chest ■ Upper gastrointestinal surgery
Active upper gastrointestinal bleeding	Recent upper gastrointestinal bleeding
History of esophagectomy	Active peptic ulcer disease, esophagitis
Perforated viscus	Esophageal varices Barrett's esophagus Symptomatic hiatal hernia Restricted cervical spine mobility ■ Atlantoaxial instability ■ Severe cervical arthritis Coagulopathy or thrombocytopenia

Adapted from Hahn RT, Abraham T, Adams MS, et al. Guidelines for performing a comprehensive transesophageal echocardiographic examination: recommendations from the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists. *J Am Soc Echocardiogr*. 2013;26(9):921–964.

CRITICAL CARE

Critical care societies have further defined competencies and applications of echocardiography in critical care beyond that established by the ASA/SCA guidelines. Several internationally based expert panels have proposed training objectives and competency-based training standards in consensus statements. Similar to the distinction between basic and advanced training in perioperative echocardiography, these statements distinguish between basic and advanced critical care echocardiography,[53-56] or a basic and expert skill set.[57] The Society of Critical Care Medicine has provided evidence-based recommendations for the use of bedside echocardiography (TEE and TTE) in the evaluation of the critically ill patient.[57]

Transesophageal Echocardiography Examination

CONTRAINDICATIONS AND COMPLICATIONS

TEE is a safe and relatively minimally invasive procedure, although echocardiographers should be aware of potential complications resulting from probe insertion and manipulation. Table 37.3 lists absolute and relative contraindications to TEE. The risks and benefits must be carefully considered in patients with oral, esophageal, or gastric disease. Hilberath and associates provide an excellent summary on the safety of TEE, with reviewed studies reporting an overall complication rate in adults of 0.18% to 2.8% and major complication rate of 0.2% to 1.2%.[58] A 2017 retrospective study reviewed recent data regarding complications in a contemporary cardiac surgery cohort.[59] Of the 7948 patients that underwent

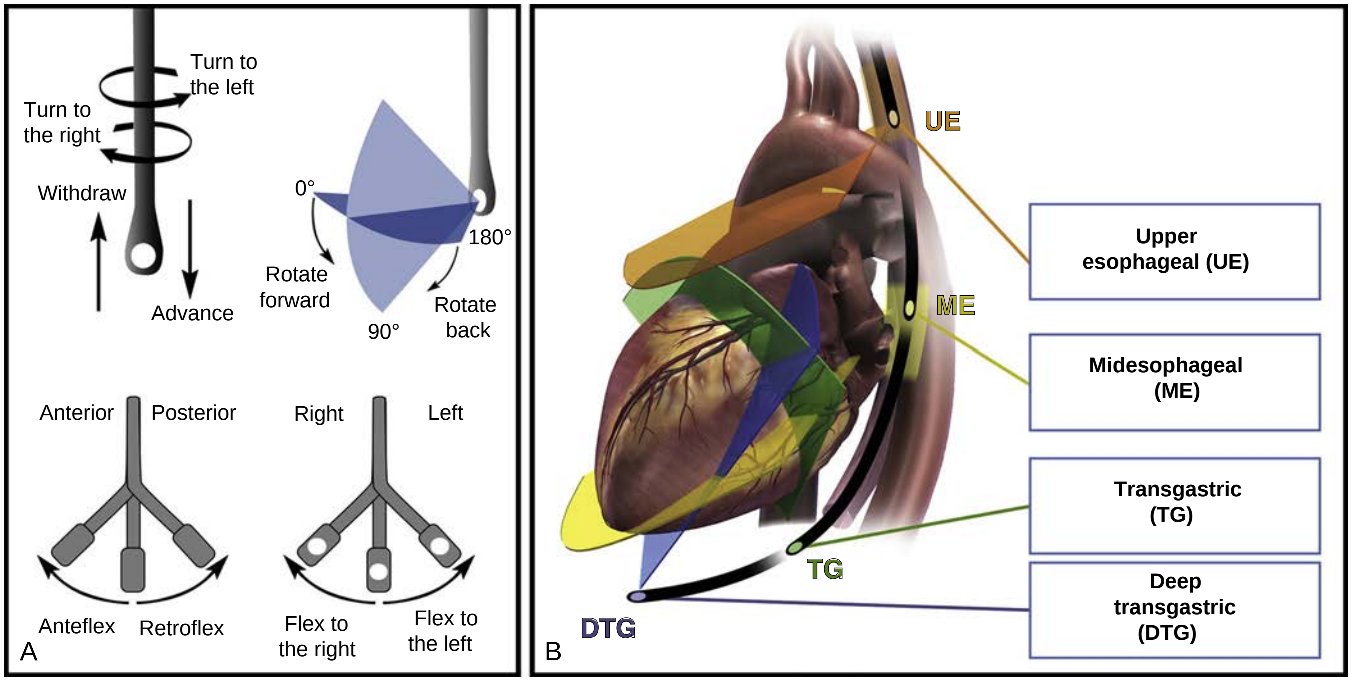

Fig. 37.5 Terminology used to describe manipulation of the transesophageal echocardiographic probe during image acquisition. (A) Terminology used for the manipulation of the transesophageal echocardiographic probe. (B) Four standard transducer positions within the esophagus and stomach and the associated imaging planes. (From Hahn RT, Abraham T, Adams MS, et al. Guidelines for performing a comprehensive transesophageal echocardiographic examination: recommendations from the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists. *J Am Soc Echocardiogr.* 2013;26(9):921–964.)

TEE, 111 (1.4%) were identified as having complications likely attributable to TEE (no other cause identified). Incidence of significant dysphagia was 0.3% and esophageal or gastric complications 0.9%. Independent risk factors associated with complications were age, body mass index, previous stroke, procedure other than isolated coronary artery bypass grafting (CABG), cardiopulmonary bypass time, and return to the operating room for any reason.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY IMAGE ACQUISITION

Probe Manipulation and Imaging Planes

TEE probe manipulation includes withdrawal/advancement, turning left/right, and angle adjustment. The large knob on the handle controls anteflexion/retroflexion and the smaller knob allows flexion to the left and right. TEE image acquisition occurs at four different levels: upper esophageal (UE), midesophageal (ME), transgastric (TG), and deep transgastric (DTG) (Fig. 37.5).

Basic Examination

The basic perioperative TEE examination serves as an intraoperative monitoring tool used to identify cardiac causes of hemodynamic or respiratory instability.[60] The basic perioperative examination includes 11 views suited to evaluating hemodynamic instability. A suggested examination sequence progresses through the 11 views as follows: ME four-chamber (ME 4C), ME two-chamber (ME 2C), ME long axis (ME LAX), ME ascending aorta long-axis, ME ascending aorta short-axis, ME aortic valve short-axis (ME AV SAX), ME right ventricular inflow-outflow (ME RV Inflow-Outflow), ME bicaval, TG midpapillary short-axis (TG SAX), descending aorta short-axis, and descending aorta long-axis.

Comprehensive Examination

A comprehensive TEE examination enables practitioners with appropriate training to fully utilize the diagnostic capabilities of TEE. Twenty-eight views (including the 11 basic views) are recommended for comprehensive assessment (Fig. 37.6). Technical aspects of image acquisition have been extensively reviewed elsewhere.[61] Echocardiographers should complete their examinations systematically to avoid missing key findings. As a result of individual patient anatomy and the time constraints of the intraoperative environment, not all views are obtained in every examination.

Epicardial and Epiaortic Imaging

While epicardial echocardiography ushered in the era of intraoperative echocardiography, its use was supplanted by TEE. In the setting of contraindications to TEE or the need for better visualization of anterior structures, epicardial echocardiography remains an alternative modality.[62]

Epiaortic ultrasound (EAU) serves as an imaging adjunct, allowing visualization of the ascending aorta and aortic arch, regions that are unable to be visualized on TEE. Detection of ascending aorta atheroma is superior with

Fig. 37.6 The 28 suggested views of the comprehensive transesophageal echocardiographic *(TEE)* examination. Each view is shown as a 3D image, the corresponding imaging plane, and a 2D image. The acquisition protocol and the structures imaged in each view are listed in the subsequent columns. The green boxes indicate the 11 views of the basic TEE examination. (Modified from Hahn RT, Abraham T, Adams MS, et al. Guidelines for performing a comprehensive transesophageal echocardiographic examination: recommendations from the American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists. *J Am Soc Echocardiogr*. 2013;26(9):921–964.)

EAU compared to that of TEE or manual palpation.[63-65] EAU impacts surgical strategy, but data as to whether this translates into improved clinical outcomes are limited and heterogeneous.[63-65] Examination guidelines and example imaging views are available.[66]

Transthoracic Echocardiography Examination

TRANSTHORACIC ECHOCARDIOGRAPHY IMAGE ACQUISITION

Three elements describe transthoracic sonographic views: (1) transducer position or window, (2) imaging plane, and (3) structures imaged. When feasible, patients should turn to their left side with the left hand resting behind the head. The main windows are parasternal, apical, subcostal, and suprasternal. Imaging motions include translation (sliding), tilting, angulation, and rotation.

Focused Cardiac Ultrasound Versus Limited Examination

With increasing use of ultrasonography at the point of care, it is important for the clinician to recognize the distinction between focused cardiac ultrasound (FoCUS, FCU) and limited TTE examination. Guidelines endorsed by several societies describe the key differences between the two examinations.[67,68] FoCUS is a simplified, point-of-care ultrasound examination that complements the physical examination (Box 37.2). FoCUS addresses specific questions within a given clinical context. Relevant abnormalities are characterized as present or absent, and questions are answered in a yes/no format. In contrast, limited TTE is broad in scope. Interpretation includes normal, pathological, and incidental findings, and quantitative techniques may be employed. Fewer images are acquired in a limited examination compared to a comprehensive examination.[67] Limited TTE requires a practitioner with advanced training and expertise.

Abnormalities identified by FoCUS require follow-up with formal comprehensive echocardiography. If FoCUS does not reveal pathology but there is clinical suggestion of cardiac disease, formal comprehensive echocardiography should also be pursued. Many FoCUS protocols exist, most including five key views: parasternal long-axis (PLAX), parasternal short-axis (PSAX), apical four-chamber (A4C), subcostal four-chamber (SC4), and subcostal inferior vena cava (SIVC) (Fig. 37.7 through 37.10; Video 37.2). Protocols often incorporate lung ultrasound. For those interested in details of image acquisition, we refer the reader to a practical introductory primer.[69]

Comprehensive Examination

A minority of anesthesiologists have the necessary training required to perform and/or formally interpret comprehensive TTE examinations. Standard imaging views occur at the parasternal, apical, and subcostal windows, plus the suprasternal notch. In addition to the views included in FoCUS, a comprehensive TTE examination includes the PLAX right ventricular outflow, PLAX right ventricular inflow, PSAX apical, PSAX mitral (basal), PSAX aortic, apical right ventricle-focused, apical five-chamber (A5C), apical two-chamber (A2C), apical three-chamber (A3C), and suprasternal notch long axis views.[70]

BOX 37.2 **Features of Focused Cardiac Ultrasound**

- Goal-directed
- Problem-oriented
- Limited in scope
- Simplified
- Time sensitive and repeatable
- Qualitative or semiquantitative
- Performed at the point of care

Qualitative Assessment

VENTRICULAR SIZE AND FUNCTION

Left Ventricle

Qualitative visual assessment of LV systolic function is the mainstay of perioperative echocardiography. Visual estimation of EF by TTE correlates well with quantitative methods[71,72] and real-time intraoperative TEE interpretation can reasonably estimate function compared to formal offline methods.[73] Wall thickening is symmetric and vigorous when LV systolic function is normal (Video 37.3). The key TEE views for global assessment of LV function include the TG SAX (Fig. 37.11), ME 4C, ME 2C, and ME LAX views (Fig. 37.12). Analogous TTE views are PSAX, A4C, A2C, and PLAX views. The TG SAX and PSAX views display distributions of all three coronary arteries.

Assessment of regional function focuses on the thickening and shortening of individual segments. Translational motion, tethering, or dyssynchrony due to conduction delay or pacing can make interpretation challenging. A 17-segment model divides the heart into six basal segments (from the mitral valve annulus to the tips of the papillary muscles), six midpapillary level segments (from the tips to the base of the papillary muscles), four apical (or distal) segments (from the base of the papillary muscles to the LV apex), and the apical cap.[74] The apical cap is difficult to visualize with TEE due to foreshortening. Segmental thickening should be assessed in the context of coronary distribution, recognizing variability among individuals. The left anterior descending artery (LAD) consistently supplies the anterior and anteroseptal segments and apical cap (Fig. 37.13). The right coronary artery (RCA) supplies the right ventricle (RV) and the basal inferior, basal inferoseptal, and mid-inferior and possibly the mid-inferoseptal segments, the latter of which may be supplied by the LAD. The left circumflex typically supplies the lateral segments, although

Subcostal inferior vena cava (SIVC)
Subcostal 4-chamber (S4C)

Fig. 37.7 Views included in the focused cardiac ultrasound *(FoCUS)* examination: parasternal long axis *(PLAX)*, parasternal short axis *(PSAX)*, apical 4-chamber *(A4C)*, subcostal 4-chamber *(S4C)*, and subcostal inferior vena cava *(SIVC)*. The parasternal window is between the third through fifth intercostal space to the left of the sternum. The apical window is near the point of maximal impulse along the mid-axillary line, often near the fifth intercostal space. The subcostal window is just below the xiphoid, along the midline or slightly to the patient's right. (Adapted from Via G, Hussain A, Wells M, et al. International evidence-based recommendations for focused cardiac ultrasound. *J Am Soc Echocardiogr*. 2014;27(7):683 e681–683 e633.)

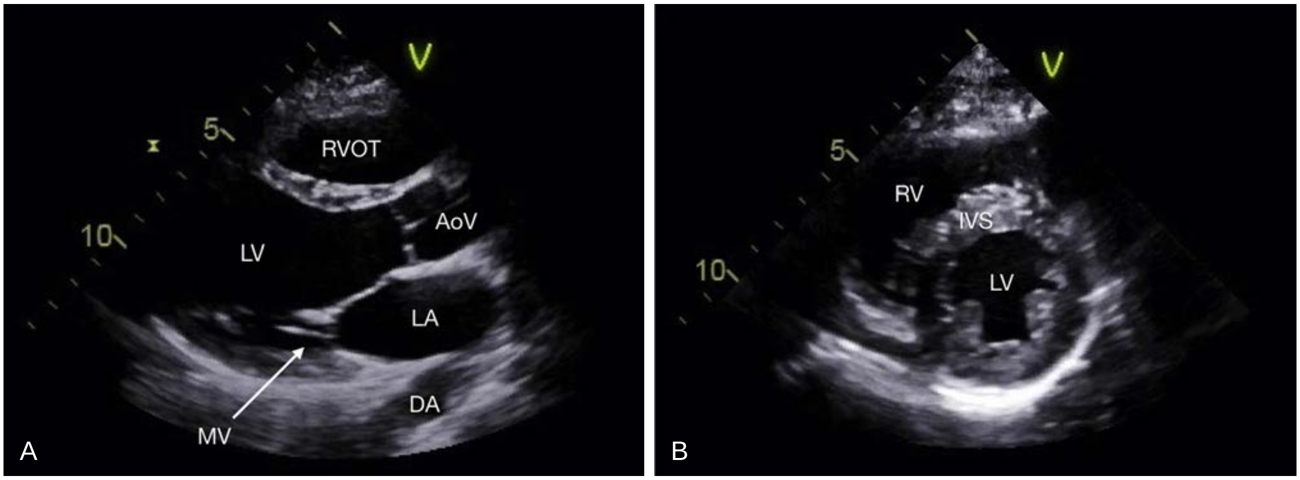

Fig. 37.8 Transthoracic parasternal views included in focused cardiac ultrasound. (A) The parasternal long axis view is shown. This view is analogous to the transesophageal midesophageal long axis view. In transthoracic imaging, anterior structures are closest to the transducer (and therefore displayed at the top of the image), while in transesophageal imaging, posterior structures are in closest proximity to the transducer (and displayed at the top of the image). (B) The parasternal short axis view is shown. This view is analogous to the transesophageal transgastric mid-papillary short axis view. *AoV*, Aortic valve; *DA*, descending aorta; *IVS*, interventricular septum; *LA*, left atrium; *LV*, left ventricle; *MV*, mitral valve; *RV*, right ventricle; *RVOT*, right ventricular outflow tract.

contributions from the LAD to the anterolateral segments or RCA to the inferolateral segments are not uncommon.[75] Each segment should be evaluated as normal/hyperkinetic, hypokinetic (reduced thickening), akinetic (minimal or absent thickening), or dyskinetic (thinning, stretching, or aneurysmal). Echocardiography is more sensitive than the ECG in detecting ischemic changes.[76]

Right Ventricle

The complex geometry of the RV makes assessment more challenging. Qualitatively, the RV should appear approximately two-thirds the size of the left ventricle, assessed in ME 4C and A4C views. Typically the right ventricle does not extend to the LV apex. RV hypertrophy suggests chronic pulmonary hypertension or the presence of cardiomyopathies.

The interventricular septum provides additional information about RV pathology. Normally, the septum curves toward the RV, and the LV cavity appears circular in short axis. In states of RV *volume* overload, the septum shifts away from the RV and flattens resulting in a D-shaped LV cavity mainly in *mid-to-late diastole* (Video 37.4). RV *pressure* overload leads to leftward septal shift and septal flattening throughout the cardiac cycle, with the changes most pronounced at *end-systole* (Video 37.5).[77]

VALVULAR FUNCTION

Qualitative assessment of valvular function begins with sequential assessment of the valve in multiple imaging planes, noting the motion of the leaflets, presence of leaflet thickening or calcification, vegetations or masses, and additional structural abnormalities (Fig. 37.14). Malcoaptation and annular dilation help define the etiology of dysfunction in regurgitant lesions. 3-D imaging modalities clarify the location of structure abnormalities.

CFD provides visual information about flow through valves. Aliasing or turbulence of forward flow through a valve should prompt evaluation for additional signs of stenosis. Further characterization of stenotic lesions is primarily quantitative in nature. Color Doppler imaging also detects

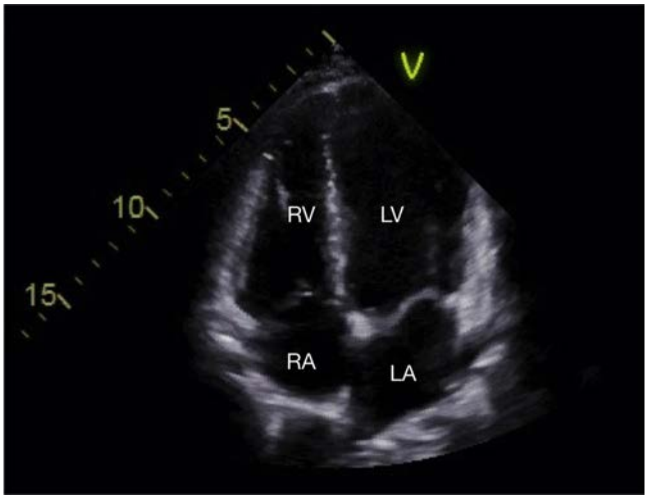

Fig. 37.9 Transthoracic apical four-chamber view. This view is analogous to the midesophageal four-chamber view in transesophageal echocardiography. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

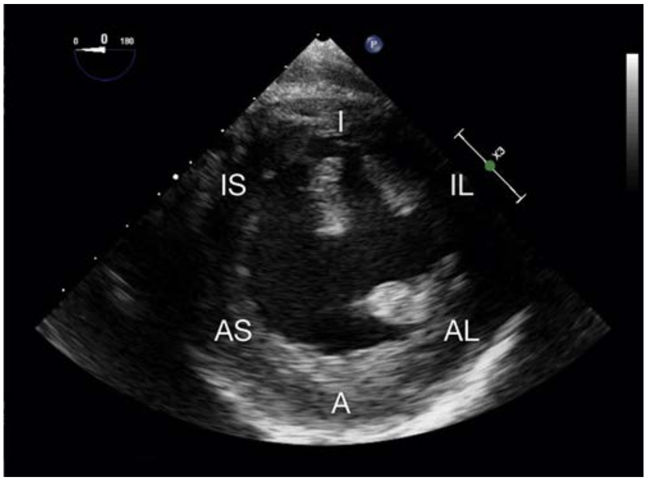

Fig. 37.11 The transesophageal transgastric mid-papillary short axis view (TG SAX) is a common view for qualitative evaluation of global left ventricular systolic function. Basal and apical segments are not visualized in this view, so midesophageal or TG LAX views should also be obtained to provide a more complete picture of the overall function. The TG SAX view includes myocardial segments supplied by each of the coronary arteries, making it useful for detection of new ischemia. The TG SAX view displays the mid inferior *(I)*, mid inferolateral *(IL)*, mid anterolateral *(AL)*, mid anterior *(A)*, mid anteroseptal *(AS)*, and mid inferoseptal *(IS)* segments.

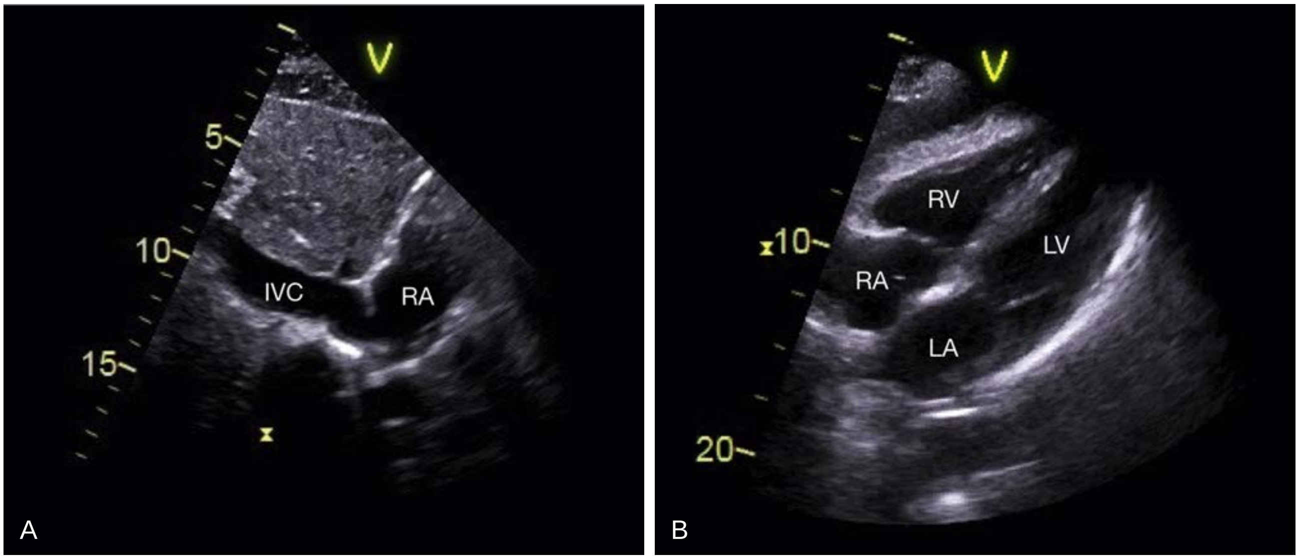

Fig. 37.10 Transthoracic subcostal views included in focused cardiac ultrasound. (A) The subcostal inferior vena cava *(IVC)* view is shown. The IVC diameter and collapsibility index are measured in this view to estimate right atrial pressure in spontaneously breathing individuals (see text). (B) The subcostal four-chamber view is shown. This view is useful for ultrasonographic examination during cardiac arrest, because it can be performed without interrupting chest compressions. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

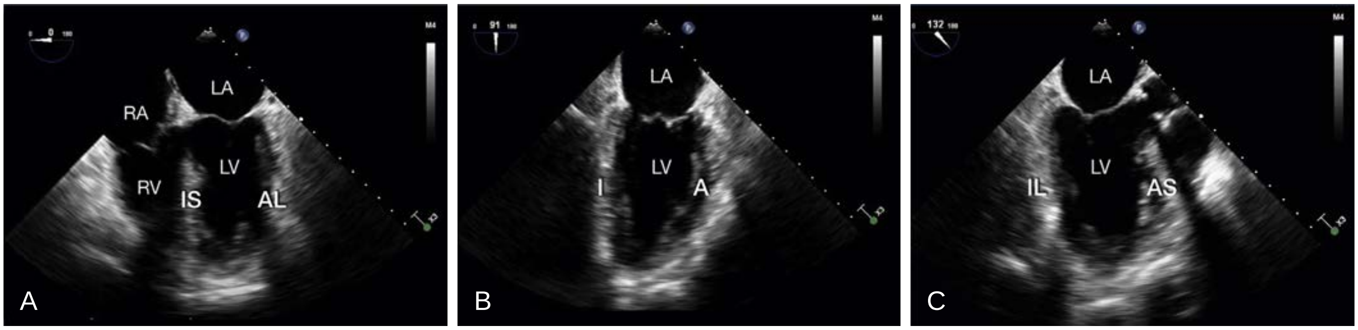

Fig. 37.12 Midesophageal views for assessing left ventricular function using transesophageal echocardiography. (A) The midesophageal four-chamber (ME 4C) view displays the inferoseptal *(IS)* and anterolateral *(AL)* walls. (B) The midesophageal two-chamber (ME 2C) view displays the inferior *(I)* and anterior *(A)* walls. (C) The midesophageal long axis view (ME LAX) displays the inferolateral *(IL)* and anteroseptal *(AS)* walls. *LA,* Left atrium; *LV*, left ventricle; *RA,* right atrium; *RV,* right ventricle.

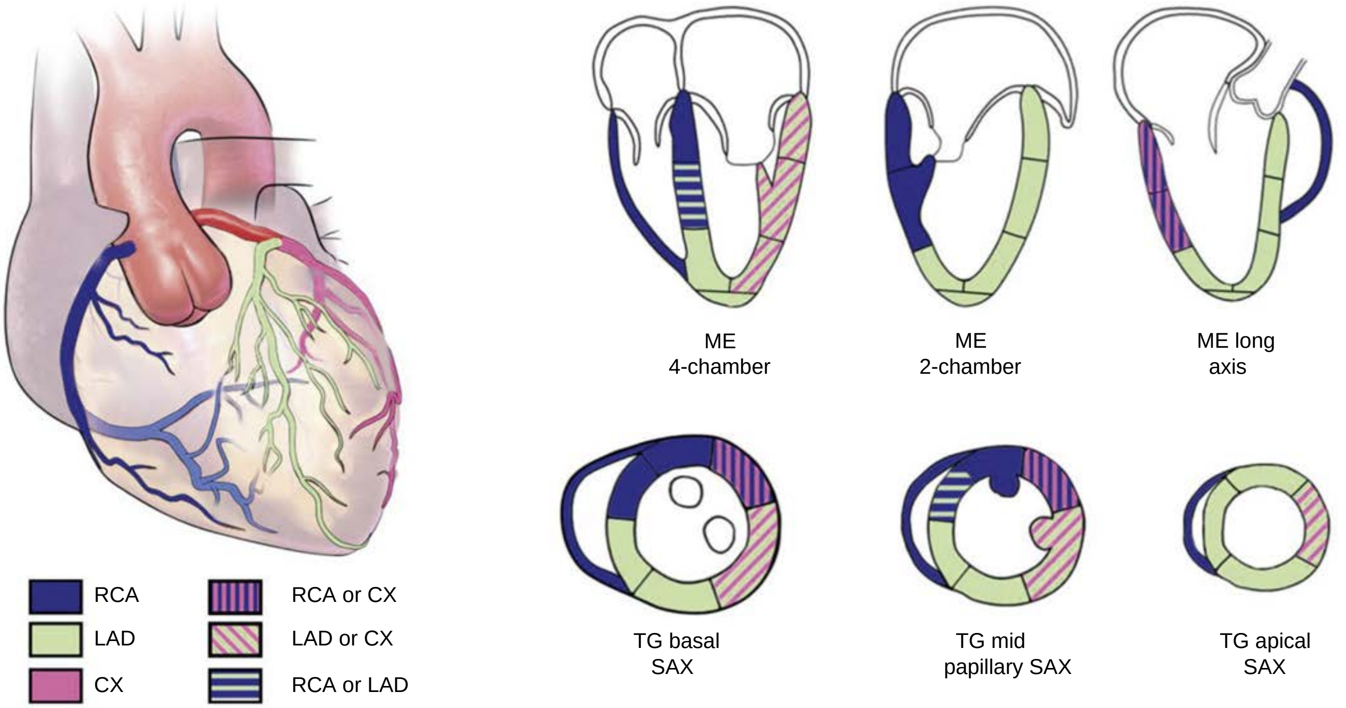

Fig. 37.13 Typical distributions of the right coronary artery *(RCA)*, the left anterior descending coronary artery *(LAD)*, and the circumflex coronary artery *(CX)* from transesophageal views of heart. The arterial distribution varies among patients. Some segments have variable coronary perfusion. *ME*, Mid-esophageal; *TG,* transgastric; *SAX*, short axis. (Modified from Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *J Am Soc Echocardiogr*. 2015;28(1):1–39 e14.)

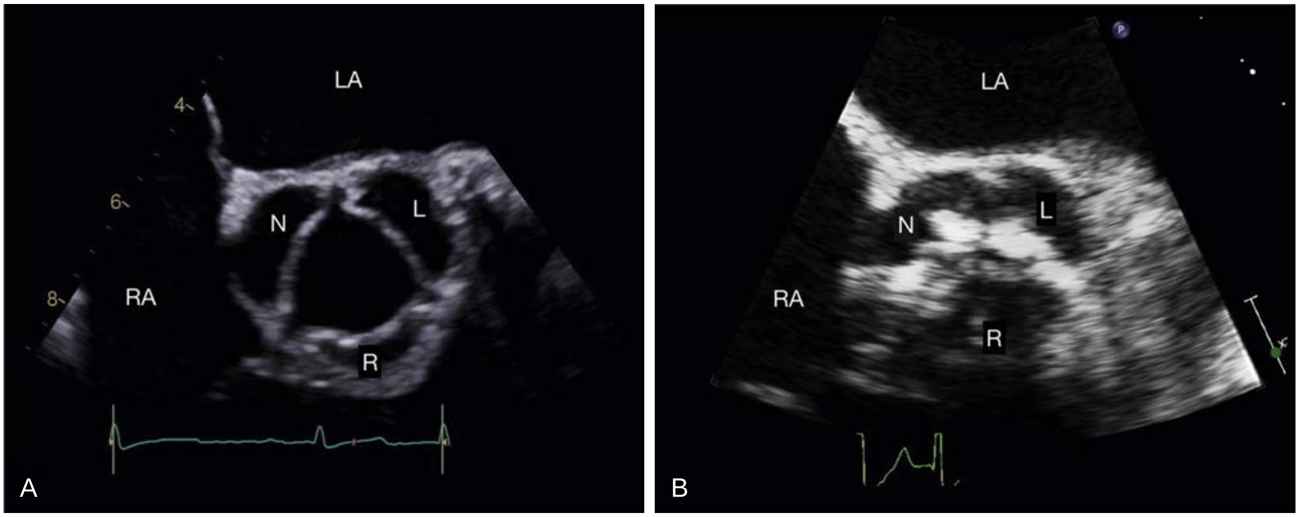

Fig. 37.14 Qualitative assessment of the aortic valve (zoomed-in transesophageal aortic valve short axis view) (A) There are three valve leaflets of normal thickness. Leaflet excursion appears normal. (B) There are three aortic valve leaflets which are severely thickened. Leaflet excursion is reduced. These qualitative findings should prompt additional quantitative assessment of valvular stenosis. *L*, Left coronary cusp; *LA,* left atrium; *N*, non-coronary cusp; *R,* right coronary cusp; *RA,* right atrium

the presence of valvular regurgitation. The three color Doppler components of a regurgitant jet are proximal flow convergence, vena contracta, and jet area (Figure. 37.15). As blood approaches the regurgitant orifice, it accelerates, forming a series of hemispheric shells of increasing velocity and decreasing area. This flow convergence region provides qualitative information about regurgitation severity and is also utilized in quantitative assessments. The vena contracta is the narrowest portion of a regurgitant jet at or immediately downstream of the regurgitant orifice.[78,79] The jet area provides information about the mechanism of regurgitation. For example eccentric regurgitation often arises from structural abnormalities while centrally originating regurgitation may be secondary in nature. The size of the jet area is subject to both technical and hemodynamic limitations, so visual estimation of jet area alone is not a reliable means of assessing regurgitation severity.

Atrial and ventricular dilation suggest chronicity of severe regurgitation; normal chamber size would be unusual in the presence of chronic severe regurgitation. Density and shape of the continuous-wave Doppler (CWD) recording of the regurgitant jet provide additional qualitative information.[79]

An important limitation of intraoperative assessment of valvular regurgitation is the hemodynamic consequences of general anesthesia, resulting in reduced preload, afterload, and contractility. General anesthesia commonly reduces the severity of MR. Pharmacologic increase of afterload may provide more representative measurements, but may also lead to significant overestimation of regurgitation severity.[80]

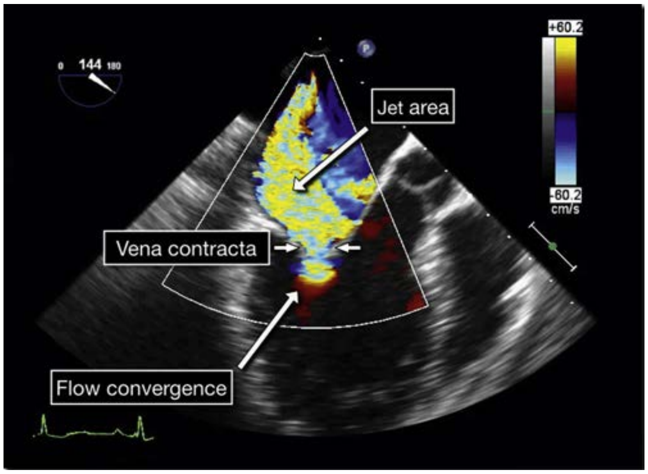

Fig. 37.15 Mitral regurgitation displaying the three components of a regurgitant jet: (1) flow convergence, (2) the vena contracta, and (3) the regurgitant jet area.

TABLE 37.4 Classification of Left Ventricular Systolic Function According to Ejection Fraction

Systolic Function	Male	Female
Normal	52%–72%	54%–74%
Mild dysfunction	41%–51%	41%–53%
Moderate dysfunction	30%–40%	30%–40%
Severe dysfunction	<30%	<30%

From Lang RM, Badano LP, Mor-Avi V, et al. Recommendations for cardiac chamber quantification by echocardiography in adults: an update from the American Society of Echocardiography and the European Association of Cardiovascular Imaging. *J Am Soc Echocardiogr*. 2015;28(1):1–39 e14.

Quantitative Assessment

VENTRICULAR SIZE AND FUNCTION

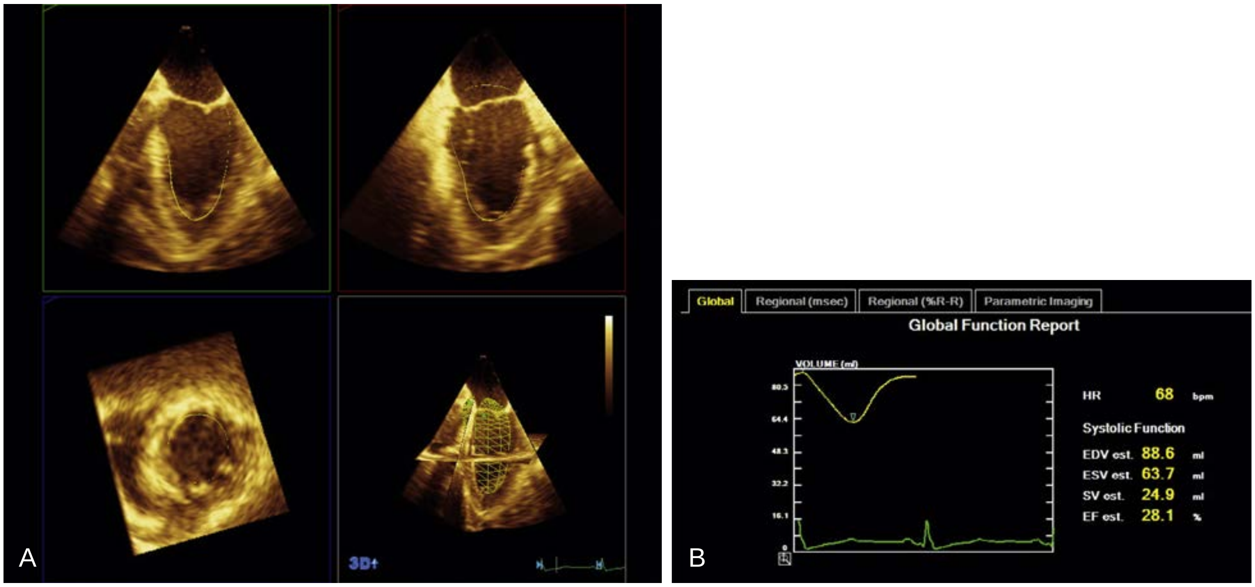
Left Ventricle

Most indices of systolic function used in routine evaluation are load-dependent, necessitating interpretation in context and serial assessments due to changing intraoperative conditions. Global systolic function is assessed by measuring the difference between an end-diastolic and end-systolic value of a parameter and dividing by the end-diastolic value. Fractional shortening uses length measurements and fractional area change (FAC) uses area measurements. Both approaches have limitations in the setting of regional wall motion abnormalities (RWMAs). Ejection fraction (EF) is the difference between the end-diastolic volume (EDV) and end-systolic volume (ESV), divided by EDV:

$$\mathrm{EF} = \frac{(\mathrm{EDV} - \mathrm{ESV})}{\mathrm{EDV}}$$

The recommended method for 2-D calculation of EF is the biplane method of disks (modified Simpson rule).[81] This requires tracing the endocardial border in two perpendicular views and assumes the LV volume consists of a stack of elliptical disks. The upper limit of normal for EDV is 74 mL/m^2 for males and 61 mL/m^2 for females; ESV is 31 mL/m^2 for males and 24 mL/m^2 for females.[81] Table 37.4 presents updated reference ranges for LVEF.[81] Assessment of EF using 3-D echocardiography (Fig. 37.16) is more accurate than 2-D echocardiography.[41] In the presence of significant valvular regurgitation, myocardial contractility may be depressed and forward cardiac output low despite a normal EF.

Additional indices of LV systolic function include DTI of the mitral annular systolic velocity (s′), myocardial performance index (MPI), and the change in LV pressure over time (dP/dt). Pulsed-wave DTI of the myocardium at the level of the mitral annulus yields a myocardial velocity profile (Fig. 37.17). The systolic velocity wave (s′) reflects the apically-directed motion of the myocardium and correlates with EF. Normal s′ reference ranges vary based on sex, age, and mitral annulus measurement size.[82] MPI assesses both systolic and diastolic performance and is calculated by the sum of isovolumetric contraction and relaxation times divided by ejection time. MPI identifies impaired global function and has prognostic value, however it is not routinely part of the perioperative examination. The change in LV pressure over time (dP/dt) derived from the CWD signal of MR provides information about LV contractility. Normal LV dP/dt is greater than 1200 mm mmHg/s; dP/dt less than 800 mmHg/s is consistent with severe dysfunction.[83] Global longitudinal strain is emerging as a technique with utility in identifying systolic dysfunction prior to decrement in EF. Normal values vary across vendor platforms, but in general, a value of −20% (or more negative) would be expected in normal systolic function (Fig. 37.18).



Global Function Report

HR 68 bpm

Systolic Function

EDV est. 88.6 ml

ESV est. 63.7 ml

SV est. 24.9 ml

EF est. 28.1 %

Fig. 37.16 Three-dimensional (3D) transesophageal echocardiographic measurement of left ventricular ejection fraction. (A) A full-volume data set of the left ventricle is displayed using multiplanar reconstruction. After manual tracing of the endocardial borders at end-diastole and end-systole in the planes displayed in the top two panels, a semi-automated endocardial border detection algorithm tracks the borders in the remaining frames. (B) The *yellow line* displays the left ventricular volume over the duration of the cardiac cycle. Measurements reported include end-diastolic volume, end-systolic volume, stroke volume, and ejection fraction. Segmental changes in volume over the course of the cardiac cycle can also be displayed.

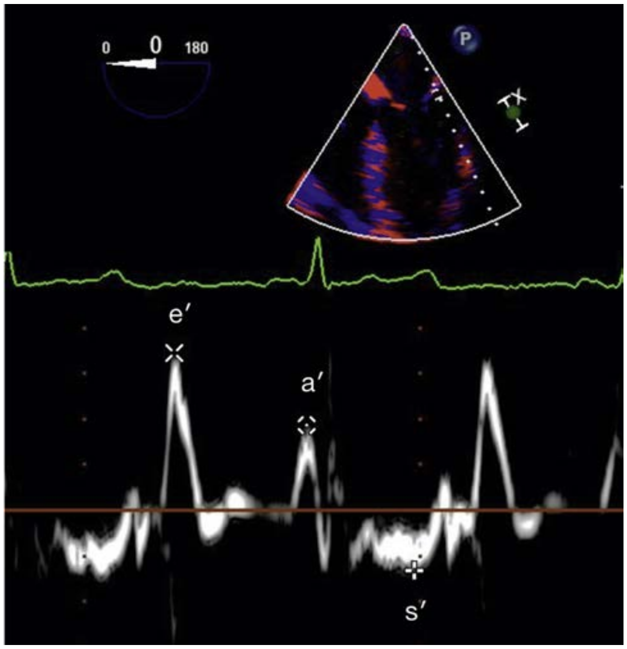


Fig. 37.17 **Spectral Doppler tissue imaging obtained at the lateral mitral annulus in the midesophageal four-chamber view.** The systolic waveform (s′) corresponds to the systolic tissue velocity. The two diastolic waveforms correspond to the early diastolic tissue velocity (e′) and the late (atrial) diastolic tissue velocity (a′). When obtained using TEE, s′ is a negative waveform (directed away from the transducer), while e′ and a′ are positive waveforms. Transthoracic acquisition of mitral annular velocity is performed in the apical four-chamber view. In TTE acquisition, the s′ waveform is positive, while e′ and a′ are negative.

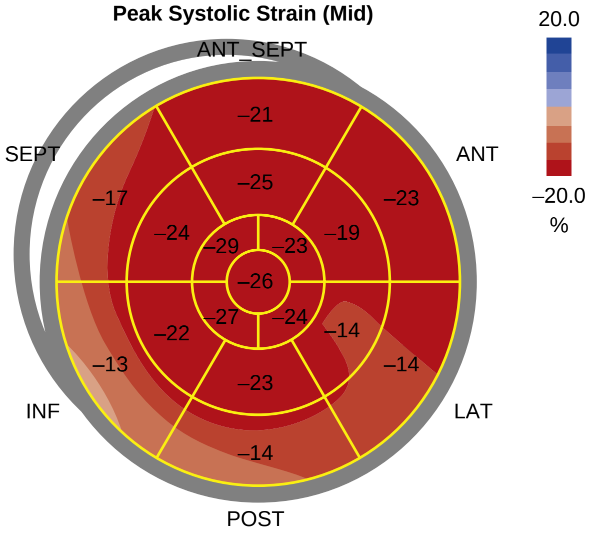

Fig. 37.18 A transthoracic "bulls-eye" plot of speckle tracking-derived global longitudinal strain obtained with transthoracic echocardiography. The image depicts the 17 segments of the left ventricle and the peak segmental systolic strain for each segment. The dark red areas represent normal strain, while the light red and pink areas represent abnormal strain. The average global longitudinal strain in this example is normal (–20.8%, not displayed in the image).

Right Ventricle

Parameters for assessment of RV function include FAC, volumetric assessments (EF), tricuspid annular plane systolic excursion (TAPSE), DTI of the tricuspid annular systolic velocity (s′), and MPI. RV FAC is obtained by tracing the endocardial border in diastole and systole, from the annulus along the free wall (excluding trabeculations) to the apex, from the apex to the annulus along the interventricular septum, and then returning to the annular starting point. RV FAC is calculated as:

$$\text{RV FAC} = \frac{\text{RV EDA} - \text{RV ESA}}{\text{RV EDA}} * 100$$

RV FAC is expressed as a percentage and has a lower limit of normal of 35%.[77] Estimation of RV EF using 2-D echocardiography requires geometric assumptions, and guidelines do not recommend its use.[77] When expertise is available 3-D RV EF is recommended, with less than 45% usually representing abnormal function.[81]

TAPSE is commonly used in TTE for evaluating RV longitudinal function, measured by aligning the M-mode cursor parallel to the tricuspid annular motion in the A4C view.[81] TAPSE less than 17 mm is consistent with RV systolic dysfunction. Parallel alignment of the tricuspid annulus with the M-mode cursor is difficult in TEE, and ME 4C measurements of TAPSE correlate poorly with TTE measurements. Alternative methods for measuring tricuspid annular motion with TEE have been explored. Anatomical M-mode measurements in ME 4C and DTG 4-chamber 0-degree views demonstrate agreement with TTE TAPSE.[84] TEE speckle tracking of tricuspid annular motion has also been demonstrated to correlate well with TTE TAPSE[85,86]; whether this will have practical perioperative applications requires further investigation. Reduction in TAPSE following cardiac surgery is well described. Whether reduced TAPSE reflects a true decrement in RV systolic function or rather geometric alteration from pericardiotomy remains controversial.[87,88]

An s′ of less than 9.5 cm/s is consistent with RV dysfunction, but like TAPSE is an index of longitudinal excursion and may be reduced after cardiac surgery. A right ventricular myocardial performance index (MPI) of greater than 0.43 by pulsed-wave Doppler (PWD) or greater than 0.54 by DTI reflects abnormal RV function.[81] RV strain and strain rate are emerging as prognostic parameters in the cardiology literature, but reference values are vendor specific and measurements are not yet routinely part of the perioperative examination.

Diastolic Function

Many complex interactions contribute to ventricular filling during diastole, but the echocardiographer should have a basic understanding of diastolic physiology and the progression of LV filling abnormalities along a continuum of impaired relaxation and decreased compliance. Myocardial relaxation primarily affects LV filling during early diastole (isovolumetric relaxation and early rapid filling), whereas the effects of ventricular compliance predominate in late diastole (diastasis and atrial contraction).

Transmitral PWD flow patterns reflect changes in LV filling and are used to characterize the stages of diastolic dysfunction. Two waveforms correspond to early rapid filling (E wave) and atrial contraction (A wave), respectively. (Fig. 37.19). The E:A ratio changes with progressive diastolic dysfunction (Fig. 37.20), and traditionally, other parameters such as isovolumetric relaxation time, deceleration time, pulmonary venous flow profiles, and propagation velocities have provided supportive information when grading diastolic dysfunction. Under normal conditions, most ventricular filling occurs during early diastole (resulting from relaxation and suction forces), and the E:A is ratio greater than 1. Grade 1 diastolic dysfunction manifests as *impaired relaxation* with decreased early diastolic filling and a compensatory increase in late diastolic filling (E < A). Relaxation remains impaired in more advanced degrees of diastolic dysfunction. In grade 2 diastolic dysfunction *(pseudonormal pattern)*, decreasing LV compliance leads to a rise in LV end-diastolic pressure (LVEDP). Ultimately an increase in left atrial pressure (LAP) increases driving pressures across the mitral valve, increasing early filling, and "normalizing" the E:A ratio. With progression to a *restrictive* pattern (grade 3 dysfunction), markedly decreased LV compliance and significantly elevated LVEDP and LAP result in very elevated peak E-wave velocity (E:A > 2) and rapid equilibration of LV and LAPs.

DTI is an important technique for evaluating diastolic function. DTI of mitral annular myocardial velocities produces two diastolic waveforms: e′ (early diastolic tissue velocity) and a′ (late diastolic tissue velocity), as shown in Fig. 37.17. Preload conditions have less effect on e′ than on the transmitral E wave. DTI e′ is reduced when impaired relaxation is present, making

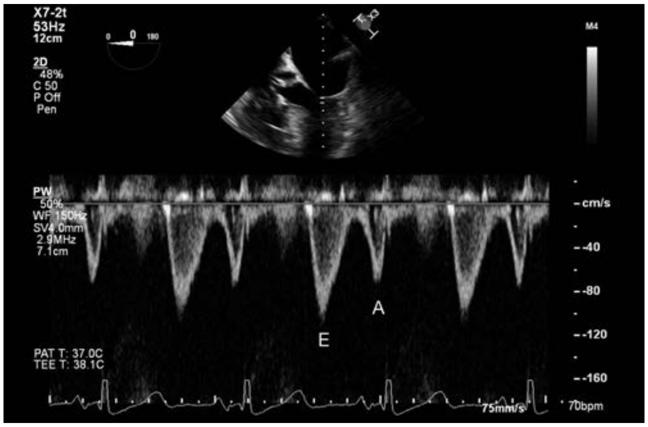

Fig. 37.19 Transmitral pulsed-wave Doppler profile demonstrating the peak early filling (E-wave) and flow due to atrial contraction (A-wave).

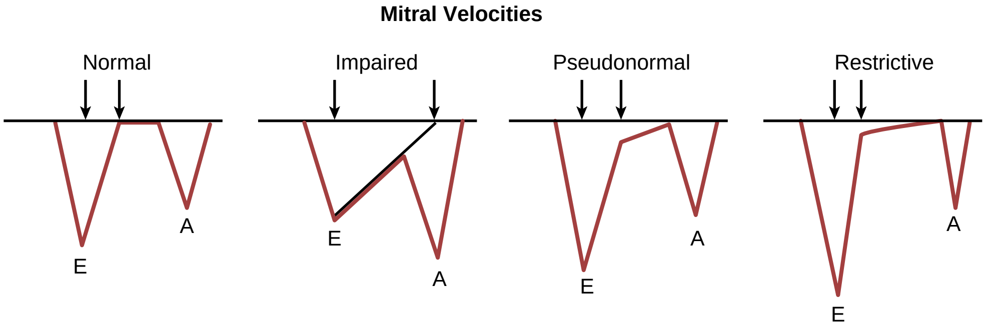

Fig. 37.20 Line drawings representing simultaneous transesophageal pulsed-wave Doppler recordings from the mitral annulus are shown for normal, impaired, pseudonormal, and restrictive left ventricular diastolic function. The black arrows mark the deceleration time of early filling, which is the interval between the peak E velocity and the point where the deceleration slope intersects the baseline. (Modified from Fig. 46.32, Desjardins G. Perioperative echocardiography. In: Miller R, ed. *Miller's Anesthesia*. 8th ed. Philadelphia, PA: Elsevier/Saunders; 2015:1396–1428.

this a useful parameter for assessing whether diastolic dysfunction is present or absent. Much has been published about site of measurement (septal vs. lateral vs. averaged) and corresponding normal thresholds. A lateral e′ velocity of 10 cm/s or greater virtually excludes diastolic dysfunction (pericardial constriction being an exception). The E:e′ ratio provides information about LV filling pressures: usually filling pressures are normal when the average E:e′ is less than 8, whereas average E:e′ greater than 14 usually reflects elevated filling pressures. However, many factors limit the interpretation of e′, including mitral stenosis, significant mitral annular calcification, mitral valve prosthesis or ring, left bundle branch block, ventricular pacing, and significant MR.[89]

Updated ASE guidelines address the perceived complexities of diastolic function assessment and propose a simplified approach to evaluation. In patients with preserved EF, four parameters should be assessed initially: e′, E:A ratio, left atrial volume index, and peak tricuspid jet annular velocity.[90] These updates reflect an appreciation that increased LA size serves as a marker of chronically elevated LVEDP. In patients with reduced EF, characterization of diastolic dysfunction begins with transmitral E:A ratio. These updated guidelines may not be generalizable to the perioperative period, and moreover, TEE cannot reliably assess LA size. There are several algorithms relevant to the perioperative period that can be referenced for a more in-depth review of diastolic dysfunction.[91-93]

VALVULAR FUNCTION

Stenosis

Aortic and mitral stenosis are the most common stenotic lesions in the perioperative setting. Fundamental to the quantitative evaluation of valvular stenosis is Doppler echocardiography. Two key concepts underlying Doppler hemodynamic measurements are the continuity principle and the pressure-velocity relationship (see *Hemodynamic measurements* section). Recommended parameters for the assessment of aortic stenosis include peak aortic velocity, mean transvalvular gradient, and valve area calculation by continuity equation (Table 37.5).[94] The peak gradient derived using echocardiography estimates the instantaneous peak pressure difference across the valve, whereas conventional catheterization data report the difference between peak LV and peak aortic pressures (peak-to-peak gradient). Dimensionless index and 3-D planimetry corroborate findings obtained by recommended methods. Discordant grading of aortic stenosis by valve area and mean gradient requires additional evaluation of LV function, stroke volume (SV), and assessment of flow reserve. Recommended parameters for assessing mitral stenosis include gradient measurements, planimetry, and pressure half-time.[95] The continuity equation and the proximal isovelocity surface area (PISA) method may be used for additional information.

Limitations exist with quantitative methods. Geometric assumptions made when using the continuity equation may lead to an underestimation of calculated valve area. Loading conditions impact flow, and as a result, impact peak velocities and calculated pressure gradients. Under general anesthesia, gradients may underestimate the severity of stenosis. In high-flow states, elevated gradients may reflect high cardiac output.

TABLE 37.5 Parameters for Evaluating Severity of Aortic Stenosis

	SEVERITY OF STENOSIS		
Parameter	**Mild**	**Moderate**	**Severe**
Peak velocity (m/s)	2.6–2.9	3.0–4.0	≥4.0
Mean gradient (mm Hg)	<20	20–40	≥40
AVA (cm^2)	>1.5	1.0–1.5	<1.0
Indexed AVA (cm^2/m^2)*	>0.85	0.6–0.85	<0.6

*In patients with small body size, aortic valve area (AVA) should be indexed to body surface area. A small valve area in a small patient may only represent moderate stenosis. Indexing to very large body surface area is controversial.

Adapted from: Baumgartner H, Hung J, Bermejo J, et al. Recommendations on the echocardiographic assessment of aortic valve stenosis: a focused update from the European Association of Cardiovascular Imaging and the American Society of Echocardiography. *J Am Soc Echocardiogr.* 2017;30(4):372–392.

Regurgitation

Recall that the vena contracta is the narrowest portion of a regurgitant jet at or downstream of the regurgitant orifice. The vena contracta width is a semiquantitative parameter for grading regurgitation severity, with cutoff values differing between valves. Pulsed-wave interrogation of flow patterns provides additional semiquantitative information. Pulmonary vein systolic flow reversal is specific for severe mitral regurgitation (MR) and hepatic vein systolic flow reversal is specific for severe tricuspid regurgitation[78].[*] Holodiastolic flow reversal in the descending aorta with velocities sustained above 20 cm/s is specific for severe aortic insufficiency.

Quantitative methods for grading regurgitation include calculation of regurgitant volume, regurgitant fraction, and effective regurgitant orifice area (EROA). Approaches include the stroke volume method, ventricular volumetric method, and the proximal isovelocity surface area (PISA) method. The radius of the previously mentioned flow convergence region is included in the PISA calculation. The details of these approaches are beyond the scope of this chapter. 3-D echocardiography allows for measurement of vena contracta area, which may be advantageous in the case of multiple jets or noncircular regurgitant orifices.

HEMODYNAMIC MEASUREMENTS

Cardiac Output

Doppler-based methods can be used to estimate SV and cardiac output (Fig. 37.21). Volumetric flow or SV can be calculated as a cylindrical volume as follows:

$$\mathrm{SV}\ \left(\mathrm{cm}^3\right) = \mathrm{CSA}\ \left(\mathrm{cm}^2\right) * \mathrm{VTI}\ (\mathrm{cm}),$$

where CSA is the cross-sectional area through which the blood flows and VTI is the velocity time integral of blood flow at that location. The VTI represents the distance the average blood cell travels during one cardiac cycle, and is

---

[*] in the absence of conditions such as atrial fibrillation, atrioventricular dissociation, or pacing with ventriculoatrial conduction.

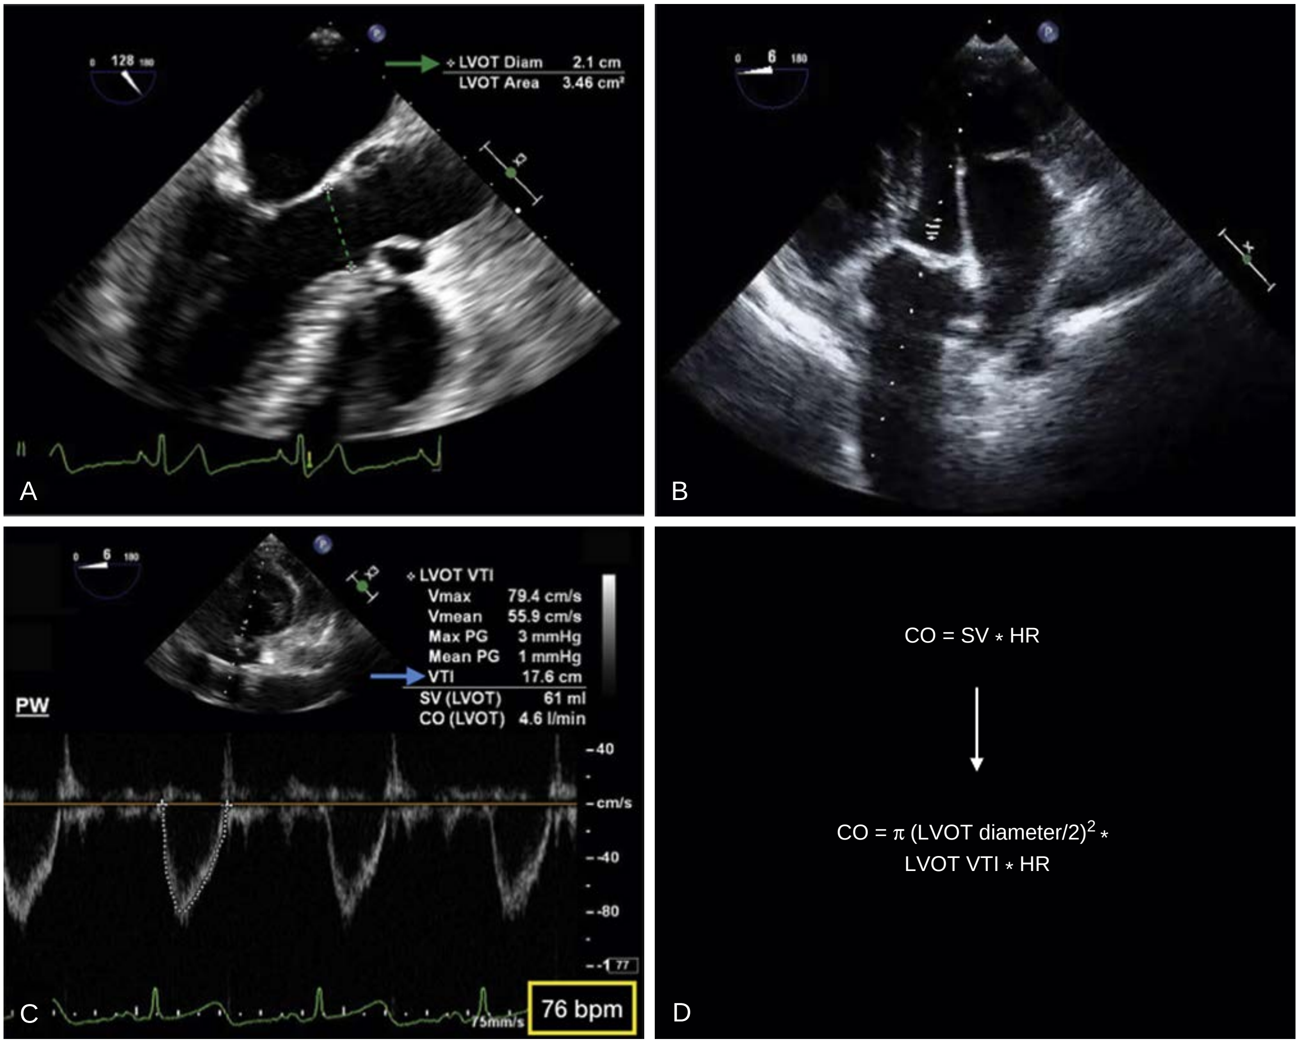

Fig. 37.21 Calculation of cardiac output (CO) using transesophageal echocardiography. (A) The left ventricular outflow tract (LVOT) diameter is measured in the midesophageal aortic valve long axis view. The cross-sectional area (CSA) of the LVOT is assumed to be circular, and is calculated as: $\text{CSA}_{\text{LVOT}} = \pi\left(\frac{\text{LVOT Diameter}}{2}\right)^2$. In this example, $\text{CSA}_{\text{LVOT}} = 3.14 * \left(\frac{2.1\text{ cm}}{1}\right)^2 = 3.46\text{ cm}^2$. (B) Velocity of blood flow through the LVOT is measured using pulsed-wave Doppler in the deep transgastric view. The velocity and diameter measurements should be performed at the same anatomic location. (C) The spectral envelope is traced to determine the area under the curve, which is equal to the velocity time integral (VTI). This represents the distance the column of blood travels with each beat and is sometimes referred to as "stroke distance." Stroke volume (SV) is the product of the cross-sectional area of the LVOT and the LVOT VTI, or $\text{SV} = \text{CSA}_{\text{LVOT}} * \text{LVOT VTI}$. (D) CO is derived by multiplying the stroke volume *(SV)* by heart rate *(HR)*, or $CO = 3.46\,cm^2 * 17.6\,cm * 76\,bpm = 4{,}628\frac{ml}{min}$. In the example provided, the machine is configured to automatically calculate stroke volume and cardiac output as displayed in panel C.

the area under the spectral Doppler envelope. Cardiac output is the product of SV and heart rate.

Cardiac output calculation is typically performed at the LV outflow tract (LVOT). The diameter is measured in the ME AV LAX view using TEE and the parasternal LAX view using TTE. The LVOT VTI is obtained in the Deep TG LAX using TEE and the A5C using TTE. Potential sources of error include inaccurate measurement of the LVOT diameter (with a squaring of any error when calculating the cross-sectional area), poor Doppler alignment with the blood flow, and measurement of the area and velocity measurements at different anatomic locations.

Many studies in surgical and ICU patients have compared Doppler-derived cardiac output (CO) to CO by thermodilution. Some authors interpret the literature to indicate Doppler-derived measurements have good agreement with CO by thermodilution.[96] Other authors, however, highlight the methodological limitations and heterogeneity of studies, and argue echocardiographic and thermodilution-derived CO cannot be used interchangeably.[97] Stronger evidence supports the use of echocardiographic-derived CO for assessing trends over time.[97]

Continuity Principle

The continuity principle states that flow rate proximal to a restricted orifice equals the flow rate through the orifice. Applying this principle to pulsatile intracardiac flow, the stroke volumes proximal to (SV_1) and at a restricted orifice (SV_2) are the same.

$$\text{SV}_1 = \text{SV}_2$$

and therefore

$$\text{CSA}_1 * \text{VTI}_1 = \text{CSA}_2 * \text{VTI}_2$$

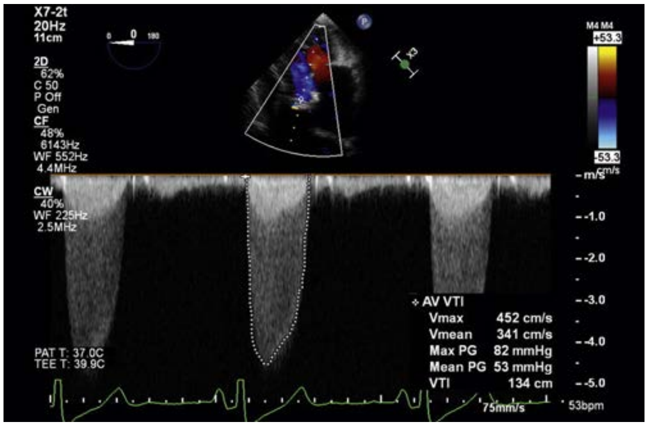

Fig. 37.22 The transvalvular pressure gradient across a stenotic aortic valve is estimated using continuous wave Doppler in the transesophageal deep transgastric view. The peak gradient is derived from the peak velocity of the spectral Doppler signal using the simplified Bernoulli equation. The mean gradient is the average of the instantaneous peak gradients throughout systole and is obtained by tracing the Doppler envelope. The ultrasound system will automatically calculate the mean pressure gradient from the tracing. The measurements in this example are consistent with severe aortic stenosis.

Common clinical applications of this equation include calculation of stenotic valve areas, prosthetic valve areas, and regurgitant orifice areas.

Bernoulli Equation

Pressure cannot be measured directly using echocardiography, however applications of the Bernoulli principle allow for estimation of gradients from velocity information (Fig. 37.22). This technique is commonly applied to quantify the severity of stenosis. The modified Bernoulli equation estimates the transvalvular pressure gradient (ΔP) as follows:

$$\Delta P = 4\left(V_2^2 - V_1^2\right)$$

where V_2 represents the peak velocity at the valve and V_1 represents the peak velocity proximal to the valve. V_1 is usually much lower than V_2 and can be ignored, simplifying the equation to:

$$\Delta P = 4V^2$$

If V_1 exceeds 1.5 m/s it should be included in the calculation.[94]

Intracardiac Pressure Estimates

Right Atrial Pressure. In *spontaneously* breathing individuals, right atrial pressure (RAP) can be estimated from the inferior vena cava (IVC) diameter and collapsibility of the IVC during inspiration (“sniff” maneuver). The IVC collapsibility index (cIVC) is defined as:

$$\text{cIVC} = \frac{(D_{\max} - D_{\min})}{D_{\max}} * 100\,\%$$

where $D_{\max}$ is the maximum diameter on expiration and $D_{\min}$ is the minimum diameter on inspiration. Table 37.6 presents a simplified approach to estimating RAP using IVC diameter and cIVC recommended by Rudski and associates.[77] In cases of intermediate RAP estimates, it is recommended to use secondary indices of elevated RAP to downgrade or upgrade the estimate.[77]

TABLE 37.6 Echocardiographic Estimation of Right Atrial Pressures*

RAP	Estimated RAP (Range) (mm Hg)	IVC Diameter (cm)	cIVC
Normal	3 (0–5)	≤2.1	>50%
Intermediate	8 (5–10)	≤2.1	<50%
Intermediate	8 (5–10)	>2.1	>50%
Elevated	15 (10–20)	>2.1	<50%

*In spontaneously breathing individuals.

In the case of intermediate estimates, the presence or absence of secondary indices of elevated RAP can be used to better characterize the pressure estimate. *cIVC*, IVC collapsibility index (see text for definition); *IVC*, inferior vena cava; *RAP*, right atrial pressures.

As proposed by/adapted from Table 3 in Rudski LG, Lai WW, Afilalo J, et al. Guidelines for the echocardiographic assessment of the right heart in adults: a report from the American Society of Echocardiography endorsed by the European Association of Echocardiography, a registered branch of the European Society of Cardiology, and the Canadian Society of Echocardiography. *J Am Soc Echocardiogr*. 2010;23(7):685–713; quiz 786–688.

Chamber Pressures. Velocity measurements of valvular regurgitation or shunt can be used to estimate chamber pressures using the simplified Bernoulli equation. The pressure gradient (ΔP) reflects the pressure difference between the chamber where blood flow originates and blood flow is received. This is expressed as:

$$P_{\text{OC}} - P_{\text{RC}} = 4V^2$$

where P_{OC} is the pressure in the originating chamber and P_{RC} is the pressure in the receiving chamber. The equation can then be rearranged to:

$$P_{\text{OC}} = 4V^2 + P_{\text{RC}}$$

A common application is estimation of pulmonary artery systolic pressure (PASP) from the maximal tricuspid regurgitant jet velocity (Fig. 37.23). Pulmonary hypertension is defined as a mean pulmonary arterial pressure (mPAP) of 25 mm Hg or greater, which corresponds to a PASP of 38 mm Hg. mPAP can be estimated from PASP as follows: mPAP = (0.61 × PASP) + 2 mm Hg.[98] Alternatively, mPAP can be estimated using the simplified Bernoulli equation and the peak velocity of pulmonary regurgitation.

Hemodynamic Failure and Shock

Hemodynamic instability and circulatory failure may occur at any phase in a patient’s perioperative care, and echocardiography provides valuable information to the operating room anesthesiologist and intensivist alike. Echocardiography enables characterization of the mechanism of shock (cardiogenic, hypovolemic, distributive, and/or obstructive)[99] and can be used for serial assessment of response to therapies.[100] Most clinicians will apply qualitative techniques during echocardiographic assessment; quantitative approaches also add valuable information when used by appropriately trained individuals.

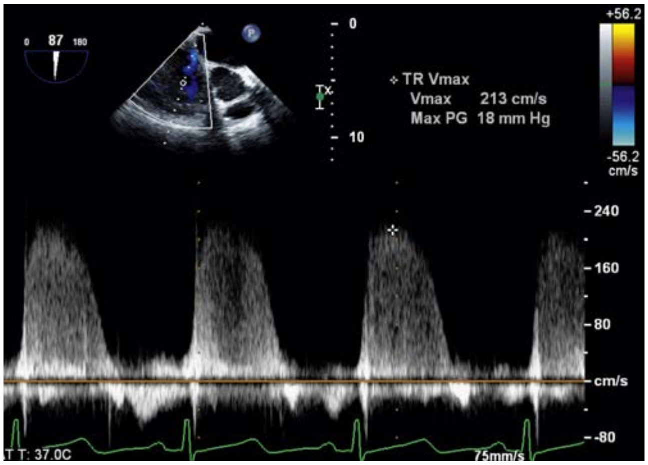

Fig. 37.23 A midesophageal modified bicaval view aligns the Doppler cursor with the tricuspid regurgitant jet. Continuous wave Doppler measures the peak systolic velocity of the tricuspid regurgitation (V_{TR}). V_{TR} reflects difference between the right ventricular systolic pressure (RVSP) and right atrial pressure (RAP), so RVSP = 4 V_{TR}^2 + RAP. In the absence of right ventricular outflow tract obstruction or pulmonary stenosis, RVSP and pulmonary artery systolic pressure (PASP) are essentially equal. In this example, the estimated PASP = 18 mm Hg + RAP.

VENTRICULAR DYSFUNCTION

Qualitative evaluation of biventricular systolic function is central to identifying the etiology of shock or hemodynamic instability. As previously mentioned, visual estimation of LVEF by experienced individuals correlates well with quantitative methods,[71,72] and can be learned easily with proper feedback.[101] A focused examination should identify whether significant myocardial dysfunction is present. Further assessment may suggest myocardial stunning or ischemia, especially if in a segmental distribution or acute in onset. This is not without limitations however, as acute decreases in preload can cause new RWMAs in the absence of ischemia.[102]

Takotsubo cardiomyopathy, a form of stress cardiomyopathy thought to result from excess catecholamine stimulation, may occur with a perioperative incidence of 1 in 6700.[103] Classically described as apical ballooning and basal hyperkinesis in the absence of obstructive coronary disease (Video 37.6), it derives its name from the similarly appearing Japanese takotsubo octopus pot trap. Additional patterns of regional involvement in stress cardiomyopathy include midventricular, basal, localized, or global.[104] Echocardiography allows evaluation of LV morphology and segmental wall motion, right ventricular involvement, and complications such as MR, LVOT obstruction, intracardiac thrombus, and cardiac rupture.[104]

SEVERE HYPOVOLEMIA

Hypovolemia leads to a decrease in LV end-diastolic area (EDA) and end-systolic area (ESA), but at baseline there is wide variability in the normal ranges.[105] For practical purposes, qualitative assessment of chamber size provides the most useful information if monitored serially in the operating room or in the setting of significant hypovolemia, where EDA will be markedly reduced. It is important to distinguish hypovolemia from distributive shock, where ESA is also decreased but the EDA area will be normal.[106] End-systolic cavity obliteration (sometimes described as "kissing walls") is frequently associated with decreased EDA and hypovolemia, but may also occur in high inotropic or vasodilatory states.[105]

As previously described, IVC diameter and cIVC can be used to estimate the RAP in spontaneously breathing individuals.[77] Central venous pressure, however, is a poor predictor of fluid responsiveness.[107] Whether cIVC predicts fluid responsiveness during spontaneous ventilation is an area of active debate,[108–111] and has been examined in several studies.[112–117] In many instances, spontaneously breathing patients with cIVC of more than 40% to 50% will respond to fluid administration,[112,115,117] but this is not found consistently,[113,114] and does not necessarily identify nonresponders.[112,115] We would encourage the reader to read the primary literature to gain a more in-depth understanding of the topic prior to attempting to use cIVC in the assessment of hypovolemia.

Predictors of fluid responsiveness applicable in patients who undergo passive mechanical ventilation, typically in the setting of critical illness, are covered in the *Critical Care* section of the chapter.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

LVOT obstruction may precipitate significant hemodynamic compromise, creating a perplexing scenario of worsening instability despite aggressive inotropic resuscitation. LVOT obstruction and systolic anterior motion (SAM) of the mitral valve are classically associated with hypertrophic cardiomyopathy. In the perioperative setting, LVOT obstruction and SAM often occur following mitral valve repair. The presence of LVOT obstruction in other susceptible populations is likely underappreciated, and probably results from a combination of anatomic predisposition and precipitating hemodynamic factors associated with enhanced LV contractility (hypovolemia, hyperkinesis, inotropes). Anatomic factors include small LV cavity, basal septal hypertrophy, and an anteriorly-displaced mitral valve coaptation zone with redundant leaflet tissue.[118] One series observed LVOT obstruction in over 20% of patients admitted in septic shock, and the presence of LVOT obstruction was associated with higher mortality.[119] SAM was present in only two-thirds of the cases of LVOT obstruction, underscoring the complex mechanisms leading to clinically relevant obstruction. In a series of perioperative rescue echocardiograms, LVOT obstruction was present in 3.6% of cases.[120]

LVOT obstruction produces high-velocity flow in the LVOT. Interrogation of the LVOT with CFD reveals flow acceleration and turbulence. Blood flow velocity exceeds the Nyquist limit of PWD, so CWD is required for quantification. Visual assessment of CFD and gradual movement of the PW sampling volume through the LV cavity and LVOT can be used to estimate the location of the obstruction. In the presence of LVOT obstruction, the spectral Doppler profile of systolic blood flow across the LVOT is dagger-shaped and mid-to-late peaking (Fig. 37.24). The

M-mode of the aortic valve will demonstrate premature leaflet closure during mid-systole (Fig. 37.25*B*). Findings consistent with SAM include anterior displacement of the mitral leaflet during systole with entrainment in the LVOT (Fig. 37.26; Video 37.7). Variable degrees of MR may be present.

CARDIAC TAMPONADE

Echocardiography readily detects pericardial fluid, which appears as an echolucent space adjacent to the heart. The physiologic significance of a pericardial effusion depends on both the volume and rate of accumulation. A large effusion may develop slowly with minimal consequence, whereas a rapidly accumulating effusion of small volume can have profound hemodynamic impact. Cardiac tamponade develops when intrapericardial pressure exceeds cardiac chamber pressures, thereby compressing the cardiac chambers. This impairs chamber filling ultimately compromising cardiac output. Hemodynamic effects of tamponade occur along a continuum.[121]

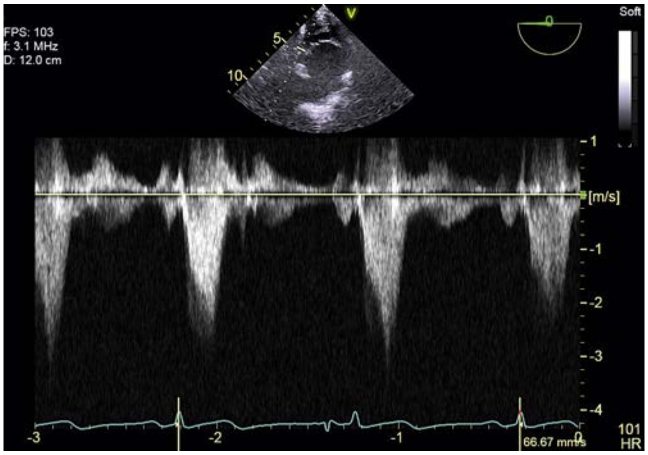

Fig. 37.24 A continuous wave Doppler signal characteristic of left ventricular outflow tract obstruction. The signal appears "dagger-shaped," with the peak velocity occurring in mid-to-late systole. In the perioperative setting, obstruction may be dynamic and unmasked by precipitating factors in susceptible individuals.

Echocardiographic findings can support the diagnosis of cardiac tamponade in the context of relevant clinical findings. When intrapericardial pressure exceeds cardiac chamber pressures, chamber collapse may occur during the respective relaxation phases. The thin right atrium typically has the lowest pressure and usually is the first chamber to show collapse or inversion, which is observed in ventricular systole (Fig. 37.27*A*; Video 37.8).[122,123] Importantly, transient right atrial collapse may be present in the absence of tamponade, and therefore is a nonspecific finding. A longer duration of atrial collapse improves the specificity of this finding.[122] RV diastolic collapse (Video 37.9; see Fig. 37.27*B*) occurs later than right atrial collapse in the progression of tamponade, and is a more specific finding. In a series of patients with moderate or large pericardial effusions, the absence of any right-sided chamber collapse had a high negative predictive value for clinical tamponade.[124] Collapse of right heart chambers may not occur in settings where baseline right-sided pressures are elevated, such as in patients with pulmonary hypertension. Following cardiac surgery, echocardiographic findings in the setting of tamponade may be atypical, including localized compression of cardiac chambers and accumulation of clot.

In spontaneously breathing patients, a dilated IVC with less than a 50% decrease in diameter with deep inspiration is a sensitive sign for tamponade. This combination of findings has poor specificity, however, because it reflects elevated central venous pressure.[125] During spontaneous ventilation in the absence of pathology, there is a normal

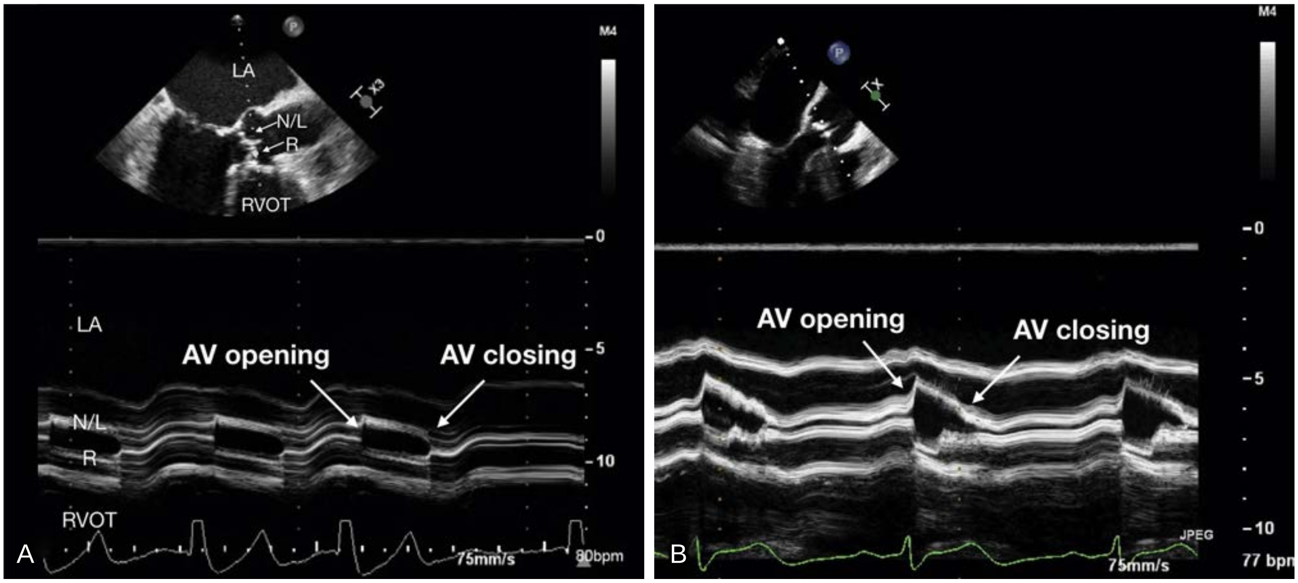

Fig. 37.25 M-mode interrogation of the aortic valve in the midesophageal aortic valve long axis view. The cursor passes through the left atrium *(LA)*, posterior aortic root, the non or left coronary cusp *(N/L)*, the right coronary cusp *(R)*, the anterior aortic root, and the right ventricular outflow tract *(RVOT)*. (A) In the absence of obstruction to flow (or other aortic valve pathology), the motion of the aortic valve leaflets during systole creates a rectangular shape. (B) In the presence of left ventricular outflow tract obstruction, the aortic valve opens normally, but closes prematurely.

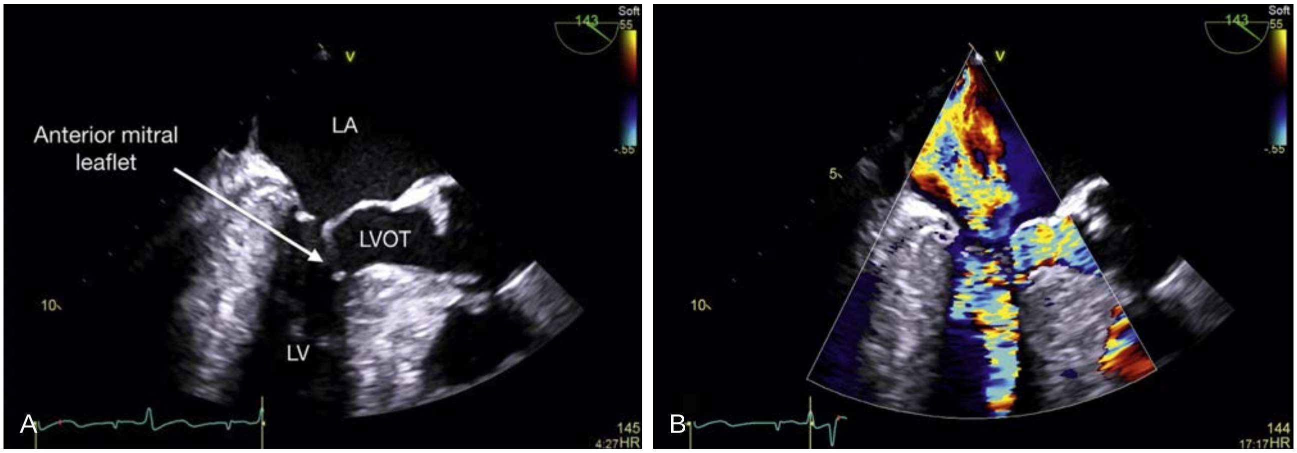

Fig. 37.26 Midesophageal long axis views without (A) and with color (B) demonstrating systolic anterior motion of the mitral valve (SAM). (A) Instead of coapting normally, the anterior mitral leaflet *(arrow)* moves into the left ventricular outflow tract *(LVOT)* during systole. This narrows the effective outflow tract and can lead to dynamic obstruction to flow. (B) Turbulent flow is visualized by color Doppler in the LVOT. In this example, there is significant mitral regurgitation associated with SAM. *LA*, Left atrium; *LV*, left ventricle.

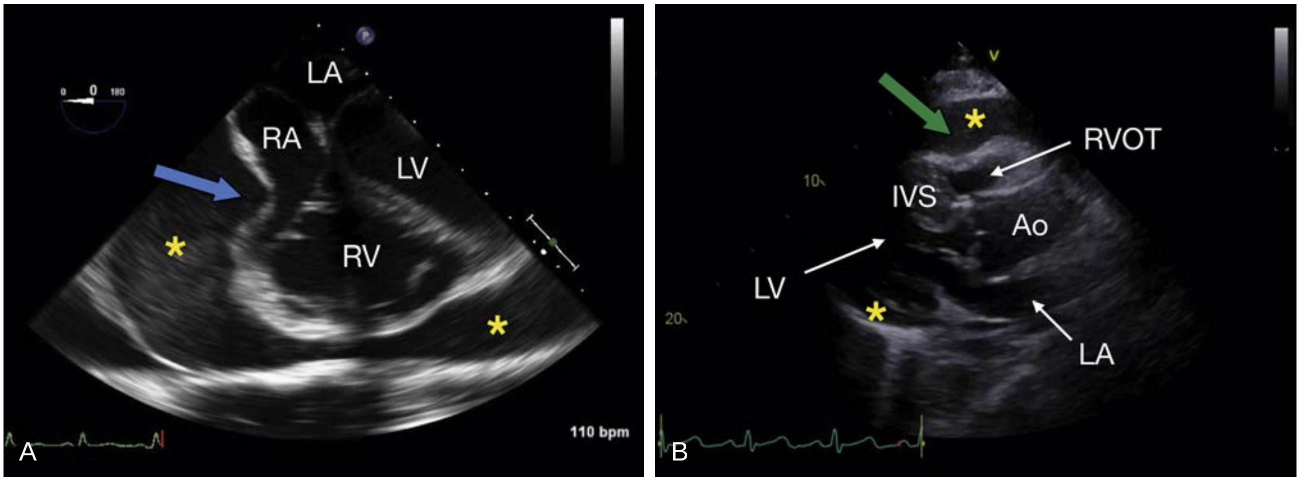

Fig. 37.27 **Echocardiographic features supporting the clinical diagnosis of tamponade.** (A) Transesophageal midesophageal four-chamber view demonstrating a large echolucent pericardial effusion (*). Right atrial collapse *(blue arrow)* is present during ventricular systole (note the red marker on the ECG tracing after the R-wave). (B) Transthoracic parasternal long axis view also demonstrating a large pericardial effusion (*). Right ventricular collapse *(green arrow)* during diastole is present (note the red marker on the p-wave of the ECG tracing). Right ventricular collapse is more specific for tamponade than right atrial collapse. *Ao,* Ascending aorta; *IVS*, interventricular septum; *LA,* left atrium; *LV*, left ventricle; *RA,* right atrium; *RV,* right ventricle.

variation in the peak transvalvular flow velocities, with transtricuspid velocities increasing during inspiration and transmitral velocities decreasing. Exaggerated respiratory variation in transvalvular flow velocities occurs in tamponade, calculated as a percentage change from expiration velocity.[121] In tamponade, there is usually a greater than 30% variation in mitral inflow velocities, and greater than 60% (absolute) variation in tricuspid inflow velocities. Exaggerated respirophasic changes in transvalvular velocities alone are insufficient to support a diagnosis of tamponade. Additionally, these findings have not been validated in patients receiving positive pressure ventilation. In fact, in an experimental animal model of tamponade, the greatest variation in mitral inflow velocities was observed during the control phase, with attenuation of the variation during tamponade.[126] Abnormal venous flow patterns in the superior vena cava (SVC) and hepatic veins can also provide supportive evidence of tamponade; however, analysis may not be feasible in at least one-third of patients due to the presence of TR, atrial fibrillation, paced rhythm, or technical inadequacy.[124] Echocardiography frequently guides pericardiocentesis procedures.

PULMONARY EMBOLISM

Acute pulmonary embolism (PE) is classified into three subgroups: high-risk (massive), intermediate-risk (submassive), and low-risk.[127,128] The presence of sustained hypotension or shock (not explained by other causes) defines massive PE. Patients with intermediate- and low-risk PE by definition are normotensive. The groups are further delineated according to RV dysfunction, myocardial injury, and other clinical features. When PE is suspected, the recommended first-line imaging modality is computed tomography angiography (CTA).[128] Echocardiography, in contrast, is not recommended in the initial diagnostic evaluation of PE.[129] When the diagnosis of PE is established, echocardiography has utility in risk stratification, prognostication, and response to therapy.[128,130]

In cases of suspected PE with hemodynamic instability or shock, obtaining a CTA may not be feasible. In this context, echocardiography has a role in refining the diagnostic assessment and management decisions.[128,131] Freely mobile intracardiac thrombus, or "clot in transit," is visualized rarely on echocardiography (<4% of cases), but more commonly in high-risk PE (22%) and is associated with worse prognosis.[132] Indirect signs of PE include RV dilation, RV dysfunction, and the 60/60 sign, which is a pulmonary ejection acceleration time of less than 60 ms with a mid-systolic notch and a TR peak gradient between 30 and 60 mm Hg.[130] Several parameters may be used to assess RV dysfunction, including "McConnell's sign," TAPSE, increased end-diastolic RV-to-LV diameter ratio (≥0.9 or 1.0), and interventricular septal flattening during systole, indicative of pressure overload.[128,130] Myocardial deformation as a marker of RV dysfunction is not widely used but is an area of investigation.[130,133]

"McConnell's sign" is an echocardiographic finding of RV hypokinesis or akinesis with apical sparing (Video 37.10). It was originally reported as having a high sensitivity and specificity for acute PE,[134] however several subsequent studies have demonstrated this finding to lack sensitivity.[135] The absence of McConnell's sign does not exclude acute PE. In many populations, McConnell's sign is highly specific. Important exceptions include patients with RV infarction[136] or pulmonary hypertension,[133] where McConnell's sign may be observed in the absence of acute PE (i.e., a nonspecific finding).

Few studies focus specifically on echocardiographic findings in the high-risk subgroup. However, in a series of 511 patients with confirmed PE, 16 of the patients met high-risk criteria.[137] Interestingly, all 16 patients had RV enlargement and hypokinesis, and at least one of the following: McConnell's sign, 60/60 sign, or right heart thrombus. Flattened interventricular system, RV free wall hypokinesis plus a RV-to-LV diameter ratio greater than 0.9, McConnell's sign, and right heart thrombus were observed significantly more frequently in patients with high-risk PE than those without.

Recent work has sought to better define the diagnostic utility of echocardiography in PE (including all risk categories), especially in light of the increasing use of point-of-care ultrasound. Meta-analysis of both formal and point-of-care TTE examinations in patients with clinical concern for PE found that echocardiographic signs of right heart strain (variably defined) had a sensitivity of 53% and a specificity of 83%.[135] In the previously mentioned series of 511 patients, over one-third of the non-high-risk patients demonstrated completely normal RV morphology and function.[137]

Intraoperative Transesophageal Echocardiography - Noncardiac Surgery

In noncardiac surgery, TEE serves two main roles: an intraoperative monitor and a rescue tool. TEE has been used in diverse operative settings including vascular, orthopedic, and transplant surgery. A comprehensive review on the topic has been published by Mahmood and colleagues.[138] The impact of TEE tends to be greater when it is used as a rescue tool versus as a monitor.[139] The extent of the therapeutic impact is difficult to quantify, however, in part because interpretation of "impact" is not uniform. Supportive or confirmatory information adds substantial value in many contexts. Therapeutic modifications reported as a result of TEE findings include initiation of pharmacologic therapy, fluid administration, and alteration in anesthetic plan or surgical procedure.[138,140,141] Continuation of patient management without changes may also be considered a relevant impact.

MONITORING ROLE

Myocardial Ischemia

Echocardiographic changes of myocardial ischemia manifest earlier than ECG changes, suggesting a potential role for TEE in the early detection of intraoperative ischemia. Current practice is to perform TEE monitoring selectively in patients with known risk factors or undergoing high-risk procedures. Early research demonstrated a 20% incidence of new or worsening RWMAs in high-risk patients.[142] Intraoperative RWMAs were infrequently associated with postoperative myocardial infarction (MI) and overall complication rate was low. Another study in the 1990s concluded that changes detected by intraoperative TEE added little incremental value in predicting risk of postoperative ischemic outcomes (death, nonfatal MI, unstable angina) compared with preoperative data and two-lead ECG monitoring.[143] The imaging capabilities of current transducers are vastly enhanced compared to those used in earlier decades, and may not reflect TEE's utility as a monitor of ischemia in the current era. A study of 54 high-risk patients undergoing vascular surgery demonstrated new RWMAs on intraoperative TEE in 43% of cases.[144] Overall incidence of postoperative MI was 11%, and all patients with MI demonstrated intraoperative RMWAs. Intraoperative TEE was a sensitive indicator of risk for postoperative MI, although there still were a substantial number of patients with "false positive" echocardiographic changes. Many questions surrounding the optimal use and potential impact of TEE as a monitor for ischemia in high-risk settings remain unanswered. In the absence of patient-specific or procedural risk factors, the routine use of TEE during noncardiac surgery to monitor for myocardial ischemia is not recommended.[51]

Liver Transplantation

Hemodynamic management during orthotopic liver transplantation is complex, with frequent periods of instability from potentially numerous causes.[145,146] At baseline, patients often have high cardiac output and low systemic vascular resistance with significant comorbidities. In the preanhepatic phase (from incision to occlusion of vascular inflow to the liver), hemodynamic alterations may result from an abrupt change in preload due to drainage of large volume ascites, hemorrhage, or surgical caval compression. TEE examination during this phase allows for characterization of dynamic changes, as well as baseline evaluation of biventricular and valvular function. During the anhepatic phase (occlusion of inflow to the liver to unclamping of the portal vein), preload to the heart is decreased. If an end-to-end interposition of the IVC is performed, complete caval occlusion is required and venovenous bypass may be used to improve preload and decrease venous congestion. A piggyback technique only requires partial caval occlusion and venous return to the heart is usually adequate without bypass. TEE findings of ventricular dysfunction, diminished cardiac output, hypovolemia, and intracardiac thrombi may be present regardless of the surgical technique. The reperfusion phase begins with release of the cross clamp from the portal vein, resulting in infusion of cold, hyperkalemic, acidotic blood. Profound instability may result and even progress to cardiac arrest. TEE provides real-time visualization of cardiac function and filling. Over 40% of liver transplant patients demonstrate evidence of inducible LVOT obstruction on preoperative dobutamine stress echocardiography,[147] making this an important diagnosis to exclude in the setting of refractory hypotension. Inspection of the IVC for high-velocity or turbulent flow is also possible with TEE.

Esophageal varices are a relative contraindication to TEE and are a relevant concern in the liver transplant population. However, the reported rate of TEE complications in liver transplantation is low, even in patients with known esophageal varices or history of upper gastrointestinal bleeding. A recent review suggests TEE to be safe in patients without grade 3 varices or active gastrointestinal bleeding.[146] Approaches to minimize risk include limited probe manipulation during the anhepatic phase and avoidance of TG and DTG views.

Lung Transplantation

Intraoperative TEE provides key information in each phase of lung transplantation in a patient population with impaired cardiopulmonary reserve.[148] Initial assessment includes evaluation for RV dilation, hypertrophy, and dysfunction, which result from long-standing pulmonary hypertension. Identification of a patent foramen ovale (PFO) may have clinical consequence if right-sided pressures exceed left-sided pressures, impacting the surgical plan. Common problems during one-lung ventilation and graft implantation include hypoxemia, hypercapnia, and elevated pulmonary vascular resistance, which may precipitate acute RV failure. Recognition of deteriorating RV function by TEE prompts initiation of inotropes or pulmonary vasodilators. Should profound instability result, TEE may provide information leading to initiation of cardiopulmonary bypass or help guide cannula placement for extracorporeal membrane oxygenation (ECMO). After reperfusion, in addition to continued assessment of biventricular function, attention turns to the pulmonary artery anastomosis and the pulmonary veins[149] for findings suggestive of kinking, thrombus, or stenosis.

Vascular Surgery/Endovascular Procedures

Patients undergoing vascular procedures are at increased risk of perioperative cardiovascular morbidity and mortality. Applications of TEE in this setting include monitoring for ischemia, assessment of systolic and diastolic function, and guidance for fluid resuscitation. In open abdominal aortic aneurysm repair, significant increases in afterload and wall tension occur with application of the cross clamp. After aortic occlusion, LVEF significantly decreases and EDV and ESV increase.[150] New or worsening RWMAs have been reported in up to one-third of patients, and occur more frequently with suprarenal versus infrarenal clamping.[151] Persistent RWMAs after several hours have been associated with postoperative MI.[151] With unclamping of vessels and ensuing instability, TEE serves as an adjunctive monitor as resuscitation proceeds. Over the past two decades, there has been a dramatic increase in endovascular repairs and a decline in open vascular procedures, consequently impacting the anticipated anesthetic concerns. Potential profound instability may be dramatically reduced, diminishing the value of intraoperative TEE in that context. However, TEE may be used to identify aortic pathology, identify landing zones, and evaluate for endoleaks.[138]

RESCUE ROLE

TEE used in the setting of unanticipated hemodynamic instability or cardiopulmonary arrest, also called “rescue” TEE, rapidly provides valuable information. Rescue TEE identifies causes of shock described earlier in the chapter (e.g., ventricular dysfunction, severe hypovolemia, LVOT obstruction, tamponade, and PE). Embolic phenomena relatively unique to the operative setting include air emboli during upright neurosurgical procedures and fat or cement emboli in orthopedic and spine surgeries.

Several series report the value of rescue echocardiography, describing its ability to identify a cause for instability or confirm expected diagnoses.[152-154] TEE aided or impacted clinical management in the majority of the cases. Rescue TEE commonly implicates LV dysfunction and hypovolemia in instability, although no diagnosis occurs with enough frequency to be predictive without performing an echocardiographic examination. In fact, in one series the most frequent finding was a normal examination or demonstration of known pathology (48%).[155] Despite a “negative” result, the TEE findings influenced management in more than half of these cases, suggesting the impact of TEE is not confined to cases demonstrating pathology. The largest reported study includes 364 rescue studies (96% TEE) performed throughout the perioperative period (55% intraoperatively).[120] The most common findings intraoperatively were hypovolemia (32%) and LV dysfunction (11%), whereas postoperatively RV (24%) and LV (22%) systolic dysfunction predominated. The findings influenced management in 59% of cases. Information can be obtained quickly (<5 minutes)[154] and may make an immediate impact. The sequence of examination and included views may vary among providers, but these should provide information swiftly. One proposed rescue protocol includes a sequence of five views: ME 4C, ME AV LAX, ME bicaval, TG SAX, and descending aorta SAX.[155]

Intraoperative Transesophageal Echocardiography - Cardiac Surgery

Numerous observational studies demonstrate the impact of intraoperative TEE on decision making in cardiac surgery. In a retrospective study of 12,566 patients, new echocardiographic findings on TEE prior to cardiopulmonary bypass (CPB) led to changes in surgical management in 7% of cases.[156] After CPB, TEE findings prompted return to CPB in 2.2% of cases. When analyzed according to surgical procedure, influential new findings were demonstrated in 5.4% of 3853 isolated CABG cases pre-CPB, and in 1.5% of CABG cases post-CPB with 0.8% requiring graft revision. A study of 521 patients undergoing CABG demonstrated new pre-CPB findings influencing the surgical plan in 11.9% of cases, and in 0.7% of cases post-CPB.[157] In valvular surgery, an analysis of 8 studies including 15,540 patients demonstrated the influence of TEE findings on surgical decision making in 11% of cases pre-CPB and 4% of cases post-CPB.[64]

When considering the impact of TEE findings on surgical interventions, limitations should be recognized. Selection bias for the use of TEE may be present in cases where it is anticipated to alter decision making, especially in CABG. Also, many studies included PFO as a diagnosis influencing the surgical plan. In the absence of high risk for hypoxemia and right-to-left shunting, optimal management of PFO when the surgical procedure does not involve atriotomy is unclear.[158] In an observational study of patients undergoing cardiac surgery, newly diagnosed PFO was not associated with increased perioperative morbidity or mortality.[159] PFO closure did not influence long-term survival, but was associated with higher risk of intraoperative stroke.

Intraoperative TEE findings provide prognostic value. Detection of RWMAs by TEE at any time during CABG is an independent predictor of postoperative MI.[160] Deterioration of regional wall motion on intraoperative TEE following revascularization is associated with higher risk of both short-term[161] and long-term[162] adverse cardiovascular events.

A general framework is useful when conducting pre-CPB and post-CPB examinations. Prior to initiation of CPB, evaluation includes assessment of overall biventricular function, aortic pathology that may affect cannulation strategy, presence of aortic regurgitation, and identification of unanticipated findings (e.g., severe valvular lesions, intracardiac thrombus). In the case of valvular surgery, diagnosis is confirmed and additional information regarding the mechanism of dysfunction is communicated to the surgeon. In minimally invasive cardiac surgery, TEE enables visualization of wires for cannulae placement and can guide percutaneous coronary sinus catheter placement. Post-CPB examination includes assessment of global and regional ventricular function, appropriate seating and function of newly implanted prosthetic valves,[163] identification of any new valvular abnormalities requiring intervention, and exclusion of iatrogenic aortic injury. Applications of TEE in the context of specific pathology and surgical procedures are outlined in the sections that follow.

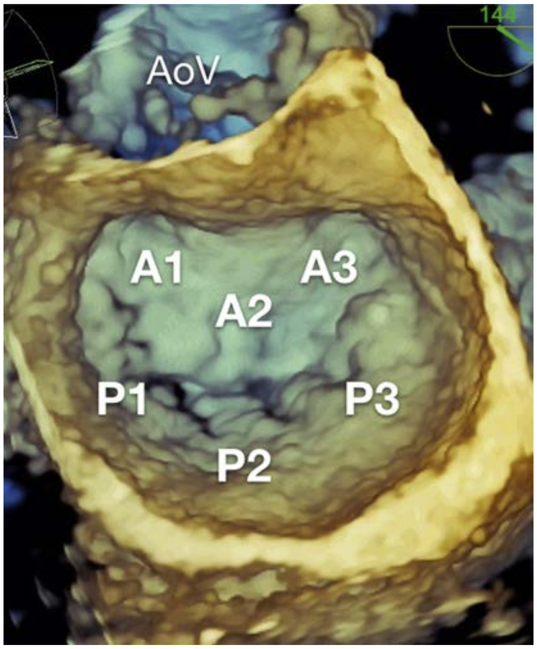

Fig. 37.28 En face display of a three-dimensional image of the mitral valve. This orientation is analogous to the viewpoint of the surgeon, and facilitates communication regarding the location of structural pathology. The scallops of the anterior *(A1, A2, A3)* and posterior *(P1, P2, P3)* mitral leaflets are labeled. *AoV*, Aortic valve.

MITRAL VALVE REPAIR

TEE imaging of the mitral valve has transformed surgical planning, particularly when assessing the suitability of attempted repair versus valve replacement for MR. Assessment of the regurgitant valve begins with examination of the structure of the valve leaflets and valvular apparatus. Primary (degenerative) MR involves abnormality of the leaflets or valvular apparatus, whereas in secondary (functional) regurgitation, the valve is structurally normal with insufficient coaptation resulting from ventricular remodeling. The mechanism of MR is classified according to Carpentier's classification of leaflet motion: type I-normal leaflet motion, type II-excessive leaflet motion, and type III-restricted leaflet motion (IIIa-restricted in systole and diastole, while IIIb is restricted in systole).[164] Quantitative assessment is performed, recognizing that intraoperative conditions often lead to underestimation of the severity of regurgitation.[80] 3-D TEE offers enhanced spatial resolution and superior accuracy in localizing leaflet pathology compared to 2-D TEE.[165-167] "En face" display of 3-D images analogous to the surgeon's intraoperative view facilitates communication regarding structural details (Fig. 37.28). The origin of the regurgitation can be precisely identified using multiplanar reformatting 3-D technology. Vena contracta area, regurgitant volume, and EROA can be quantified using 3-D techniques with potentially improved accuracy. At present, 3-D quantitative analyses are labor-intensive and time consuming, making them largely impractical for routine intraoperative assessments.

Valve repair is often feasible in degenerative disease with isolated prolapse or flail, and moderate or less annular dilation.[79] Bileaflet disease (Barlow disease), severe annular dilation, rheumatic deformities, and severe mitral annular calcification are predictors of unsuccessful repair.[168] Regurgitation recurs in a substantial proportion of patients with ischemic MR following repair. LV remodeling and leaflet tethering with apical displacement of the coaptation point impact the feasibility of repair of ischemic MR. Quantitative measurements include assessment of the tenting height (the perpendicular distance from the plane of the mitral annulus to the point of leaflet coaptation) and systolic tenting area (area enclosed by the mitral annular plane and closed leaflets). Tenting height of 11 mm or greater is associated with recurrent MR. On intraoperative TEE, mitral diastolic annular diameter of 37 mm or greater, tenting area of 1.6 cm^2 or greater, and severe MR are associated with high probability of repair failure.[168]

Additional considerations in the pre-bypass echocardiographic evaluation include predictors of post-repair SAM of the anterior mitral leaflet, which commonly reflect anterior displacement of the coaptation point. This may take the form of reduction in distance between the coaptation point and the septum (C-sept distance < 2.5 cm) or a relatively elongated posterior leaflet (anterior to posterior leaflet ratio of ≤ 1.3 or posterior leaflet height > 1.5 cm), and narrow aorto-mitral angle.[169,170] Other SAM predictors include basal septal hypertrophy (>15 mm), small LV cavity, and anterior displacement of the papillary muscles.

Immediately following separation from CPB, echocardiography assesses for significant regurgitation, stenosis, or dynamic LVOT obstruction due to SAM. Stability of the ring and normal leaflet motion should be demonstrated. Any residual regurgitation should be no more than mild and transvalvular. Should SAM occur, management steps include administration of fluid and discontinuation of any inotropes. If SAM persists, the next therapeutic maneuvers are administration of beta blockers and increase in afterload. The effect of these interventions can be readily observed on TEE. SAM will improve or resolve in most patients, and long-term follow-up demonstrates low incidence of SAM, favoring conservative management.[171] Persistence of significant SAM requires revision. Assessment of mitral inflow typically involves measurement of transvalvular gradient, recognizing this is dependent on cardiac output.

TRICUSPID VALVE REPAIR

Increased recognition of the adverse prognostic effects of TR has stimulated interest in tricuspid valve pathology. After surgical correction of left-sided valvular heart disease, severe secondary TR often fails to improve. Even mild or moderate secondary TR may progress if uncorrected. Current AHA/ACC guidelines recommend tricuspid valve repair for severe TR at the time of left-sided valve surgery.[50]

The decision to intervene upon less than severe TR at the time of left-sided valve surgery is more complex. When not intervened upon at the time of left-sided valve surgery, mild or moderate TR progresses in approximately 25% of individuals.[50] Annular dilation strongly factors in the decision to intervene early. Individuals with mild or greater TR and either annular dilation (diastolic diameter of > 40 mm or > 21 mm/m^2) or evidence of prior right-sided heart failure can benefit from concomitant tricuspid valve repair (type IIa recommendation). In the absence of tricuspid annular dilation, tricuspid valve repair may be considered during left-sided surgery when moderate TR and pulmonary hypertension are present (type IIb recommendation).

The structure of the tricuspid valve is complex. Because the annulus is nonplanar and the valve leaflets unequal in size, it can be difficult to visualize all three leaflets in the same 2-D imaging plane. The anterior location of the valve (far field in the scanning plane) and the thin leaflets also limit 2-D TEE imaging. Measurement of annular diameter by 2-D TTE typically occurs in the A4C view,[172] however this one measurement may not accurately reflect the degree of dilation and has underestimated maximal diameter compared to 3-D TEE.[173] Studies of 3-D TEE have enhanced our understanding of annular dilation in the septal-to-lateral dimension, the progression from an oval to more circular shape, and the accompanying changes in annular dynamism.[174,175] Use of 3-D color may improve quantitative assessment of regurgitation severity,[172] however in the intraoperative environment, underestimation of TR is not unexpected. Technologies using 3-D TEE will continue to fill a larger role in the evaluation of TR.

AORTIC DISSECTION

Acute type A aortic dissection has high morbidity and mortality. Accurate diagnosis is paramount to rapid treatment. The preferred diagnostic approach under most circumstances is CTA, which identifies dissection with a sensitivity of 100% and specificity of 98%.[176] In some cases, TEE may be performed more readily than CTA. TEE performs with slightly lower sensitivity (86%-100%) and specificity (90%-100%), although in many studies TEE performs with comparable specificity to CTA.[176,177] TEE imaging challenges include a blind spot in visualization of the distal ascending aorta and proximal arch due to interposition of the left mainstem bronchus between the aorta and esophagus. Imaging artifacts in the near field are common because of reverberation and refraction (especially in the presence of a pulmonary artery catheter) and may be erroneously interpreted as an intimal flap.

Intraoperative TEE during surgical intervention further defines features of the dissection. Measurements of the aortic annulus and root are performed, effacement of the sinotubular junction excluded, and structure and function of the aortic valve assessed. Mechanisms of aortic insufficiency include regurgitation due to a bicuspid valve, extension of the intimal flap to the annulus causing asymmetric leaflet prolapse, malcoaptation due to root dilation, and prolapse of the intimal flap preventing complete leaflet closure.[178] This mechanistic information influences whether valve repair is feasible and may lead to modification of the planned surgical procedure.[179] Further assessment includes examination of the true and false lumens. Blood flow may be visualized across the intimal flap. Usually the true lumen will expand during systole, which can be appreciated using M-mode echocardiography. The false lumen often demonstrates diastolic expansion and spontaneous echo contrast. Due to the complex nature of some dissections, it may be difficult to determine the true and false lumens accurately.

MECHANICAL CIRCULATORY SUPPORT (MCS)

Durable Mechanical Circulatory Support

Approximately 2500 durable left ventricular assist devices (LVADs) are implanted annually in North America, nearly half of which are destination therapy.[180] Intraoperative TEE confirms known pathology and is integral for identifying abnormalities that may require additional intervention.[181-183] Prior to implantation, echocardiographic assessment includes examination of biventricular size and function, and evaluation for intracardiac shunt (including PFO) and intracardiac thrombus. Preexisting valvular dysfunction is characterized. Greater than mild aortic insufficiency, moderate or greater mitral stenosis, and moderate or greater tricuspid insufficiency may require additional valvular procedures. An existing mechanical aortic valve may require replacement due to the risk for thrombus formation secondary to decreased transvalvular flow after LVAD implantation. Echocardiographic predictors of RV failure following LVAD implantation have been an area of considerable investigation, including the newer myocardial deformation techniques. At this time no measures reliably predict the need for biventricular mechanical support.[183]

During device implantation, TEE guidance facilitates appropriate apical positioning of the inflow cannula. Postimplantation assessment includes LV size, degree of LV decompression, RV function, reassessment for PFO, and frequency and extent of aortic valve opening. Assessment of LV unloading includes determination of overall chamber size and the position of the interventricular septum, which should be midline rather than bowing toward either chamber. As LVAD speeds are increased, parameters are frequently reassessed, especially if there is concern for marginal RV function. An appropriately positioned inflow cannula should be in the apex, directed toward the mitral valve, and should not interfere with the subvalvular apparatus. Acute angulation of the inflow cannula toward the septum may lead to cannula obstruction. Typical inflow velocity is 1.5 m/s or less. Imaging artifacts with newer-generation LVADs may preclude spectral Doppler and color flow assessment of the cannula. The outflow graft–ascending aorta anastomosis may be visualized in ME or UE views. An outflow velocity of 2 m/s or greater raises concern for obstruction, although normal values for newer generation devices may be higher.[183,184] The mid-portion of the outflow graft can also be visualized along the right side of the heart, but should not cause compression.

Temporary Mechanical Circulatory Support

Common percutaneous devices for temporary MCS include intraaortic balloon pumps, ECMO, Impella percutaneous ventricular assist devices (Abiomed, Danvers, MA), and TandemHeart percutaneous ventricular assist devices (CardiacAssist, Pittsburgh, PA). Surgically implanted devices are options when longer duration of temporary support is anticipated. Appropriate device position depends on the specific technology and may be facilitated by TEE guidance.[183,185] When assessing for myocardial recovery, TEE may add to the information provided by hemodynamics and has been incorporated into some venoarterial extracorporeal membrane oxygenation weaning protocols.[186]

CONGENITAL HEART SURGERY

In congenital heart surgery, TEE provides diagnostic information, contributes to surgical planning, identifies residual defects after repair, and influences postoperative medical management.[187] As TEE has been more widely applied in congenital heart surgery, contemporary studies report pre-CPB findings altering the surgical procedure in approximately 1% to 9% of cases and residual lesions requiring surgical revision in approximately 4% to 6% of cases, with greater impact in more complex cases.[188-191] When including return to CPB for brief ventricular support or an assist device, TEE has impacted surgical interventions in close to 13% of cases.[189] TEE further influences pharmacologic management and provides new diagnostic information. Epicardial imaging may provide complementary information to TEE when assessing pulmonary arteries and coronary arteries during pediatric congenital heart surgery.[192] There is a limited body of literature suggesting that intraoperative TEE in pediatric cardiac surgery has cost-saving benefits.[193]

OTHER SURGICAL PROCEDURES

The intraoperative echocardiographer encounters many scenarios where valvular disease requires surgical intervention, including native and prosthetic valve dysfunction. TEE confirms the preprocedure diagnosis and may refine the location of structural abnormalities. Surgical intervention for endocarditis prompts TEE evaluation for vegetations on other valves and the presence of abscess cavities. Other cardiac surgical procedures that commonly rely on intraoperative TEE include minimally invasive approaches (valve repair/replacement and CABG), cardiac mass removal, heart transplantation, and pulmonary thromboendarterectomy.

Intraprocedural Transesophageal Echocardiography- Structural Heart Interventions

Innovations in percutaneous technologies have led to exciting growth in the management of structural heart disease, extending treatment to patients with previously limited therapeutic options. The section that follows elaborates on the role of echocardiography in a few of these percutaneous procedures.

TRANSCATHETER AORTIC VALVE REPLACEMENT

First approved for commercial use in Europe in 2007 and the United States in 2011,[194] transcatheter aortic valve replacement (TAVR) has revolutionized the treatment paradigm for aortic stenosis. TAVR is indicated for the treatment of extreme- and high-risk populations with severe symptomatic aortic stenosis and it is a reasonable alternative in patients with intermediate surgical risk.[195] The number of procedures performed annually continues to grow.[196] Comprehensive resources are available detailing the periprocedural echocardiographic imaging for TAVR.[197,198]

Valve Sizing

Annular dimensions guide appropriate sizing of the transcatheter valve. The preferred imaging modality for annular size measurements is multidetector computed tomography (MDCT).[199] As compared to MDCT, 2-D TTE and TEE routinely underestimate annular size because of the elliptical shape of the aortic valvular complex.[200,201] 3-D TEE yields larger annular size measurements than 2-D TEE.[202,203] Measurements obtained by 3-D TEE may underestimate[204-206] or be comparable to[200,203,207] MDCT measurements. Both MDCT[208,209] and 3-D TEE[205,210] have been used to predict postimplantation paravalvular regurgitation. Automated 3-D TEE software is under investigation, demonstrating reproducibility and good agreement with MDCT-based prosthesis sizing.[211,212]

Intraprocedural Examination

At the beginning of the procedure, echocardiographic assessment includes not only evaluation of the aortic valve, but also determination of biventricular function, assessment of other valvular abnormalities, characterization of any preexisting pericardial effusion, and identification of other features of procedural significance, including small LV cavity and basal septal hypertrophy. When the procedure is underway, wire and device position can be guided with echocardiography, although often fluoroscopy is the primary tool. Ideal valve position prior to deployment depends on valve design (e.g. self-expanding or balloon-expandable).

Following implantation of the valve, an integrated assessment using fluoroscopy, invasive hemodynamics, and echocardiography provides information about valve position, severity of paravalvular regurgitation, and transvalvular gradients. Early recognition of unfavorable results allows for further interventions such as balloon dilation or implantation of a second device. Echocardiography excludes other complications, including functional mitral stenosis, new pericardial effusion, new RWMAs (potentially due to coronary obstruction), and aortic injury.

Transesophageal Echocardiography Versus Transthoracic Echocardiography

Active debate surrounds the optimal anesthetic approach[213] and intraprocedural imaging strategy[214] for transfemoral TAVR. Original TAVR clinical trials were performed under general anesthesia with intraprocedural TEE.[215,216] However technology has improved and procedures are of shorter duration, making procedures under monitored anesthesia care or with nursing-administered sedation feasible. High-volume centers employ these techniques along a spectrum, ranging from 100% general anesthesia, to using both sedation and general anesthesia, to nearly 100% of cases with sedation.[217] In the United States from 2012 to 2015, use of general anesthesia decreased from 97.6% to 82.6%, while use of moderate sedation increased from 2.2% to 16.6%.[196] In a 2015 survey of 250 centers representing 38 countries, general anesthesia was the most common technique in 60.1% of centers, with 39.5% of the total centers reporting exclusive use of general anesthesia.[218] Forty-six percent of centers reported systematic use of intraprocedural TEE; 62% and 31% of centers reported use of TEE and TTE, respectively, for assessment of aortic regurgitation following device implantation.[218] Despite the increasing shift away from general anesthesia and consequently TEE, use of intraprocedural TEE may be preferable for monitoring patients at high risk for coronary occlusion or annular rupture, reducing intravenous contrast exposure in high-risk patients, and providing secondary measurements for valve sizing.[219]

Because intraprocedural TEE is often performed in the setting of general anesthesia, it is difficult to assess the independent effects of general anesthesia or echocardiographic modality on outcomes. In a study comparing general anesthesia to nongeneral anesthesia in transfemoral TAVR, the majority of patients receiving general anesthesia had intraprocedural TEE, while TEE was performed in a minority of cases without general anesthesia. Propensity-matched analysis adjusted for type of anesthetic did not demonstrate significant differences in rates of successful valve deployment, more-than-mild aortic regurgitation, or other complications in patients that had an intraprocedural TEE versus those that did not.[220] A retrospective study of 454 consecutive patients undergoing transfemoral TAVR with either TTE under moderate sedation ($n = 234$) or TEE under general anesthesia ($n = 220$) showed no difference in the incidence of at least mild paravalvular regurgitation at hospital discharge (33% in TTE group vs. 38% TEE group, respectively $P = .326$).[221] The TTE group did however have a significantly higher incidence of second valve implantation (7% vs. 2%, $P = .026$) and postdilation (38% vs. 17%, $P < .001$).[221] Many retrospective studies are confounded by chronology bias—use of primarily TEE early on with a transition to TTE occurring after the development of procedural expertise. Additionally, findings with earlier generations of valves may not be applicable to the current generation used in clinical practice. While current studies do not allow definitive conclusions to be drawn about TEE versus TTE in TAVR, they represent initial steps in tackling these questions.

TRANSCATHETER MITRAL VALVE REPAIR

Percutaneous treatment of MR with the MitraClip procedure (Abbott Vascular-Structural Heart, Menlo Park, CA) uses a clip to grasp and appose the free edges of the anterior and posterior mitral leaflets at the site of regurgitation, creating a double orifice similar to that of the surgical Alfieri technique. In the United States, MitraClip was initially approved for the treatment of severe primary (degenerative) MR in patients with prohibitive surgical risk. In Europe, percutaneous valve repair has also been used for the treatment of secondary (functional) MR. In both patient populations, impact of treatment and long term outcomes are areas of active investigation.[222] Several randomized trials now include patients with secondary MR[223–225], and the body of literature is rapidly growing. As of 2019, indications for MitraClip therapy in the United States have expanded to include patients with significant secondary MR despite optimal medical therapy.

Echocardiographic imaging is essential in determining the suitability for the procedure, providing intraprocedural guidance, and evaluating procedural success.[226] Preoperative echocardiography characterizes the anatomic features of the valve, examines the subvalvular apparatus, and provides qualitative and quantitative assessments of the severity of the regurgitation. Optimal morphologic features

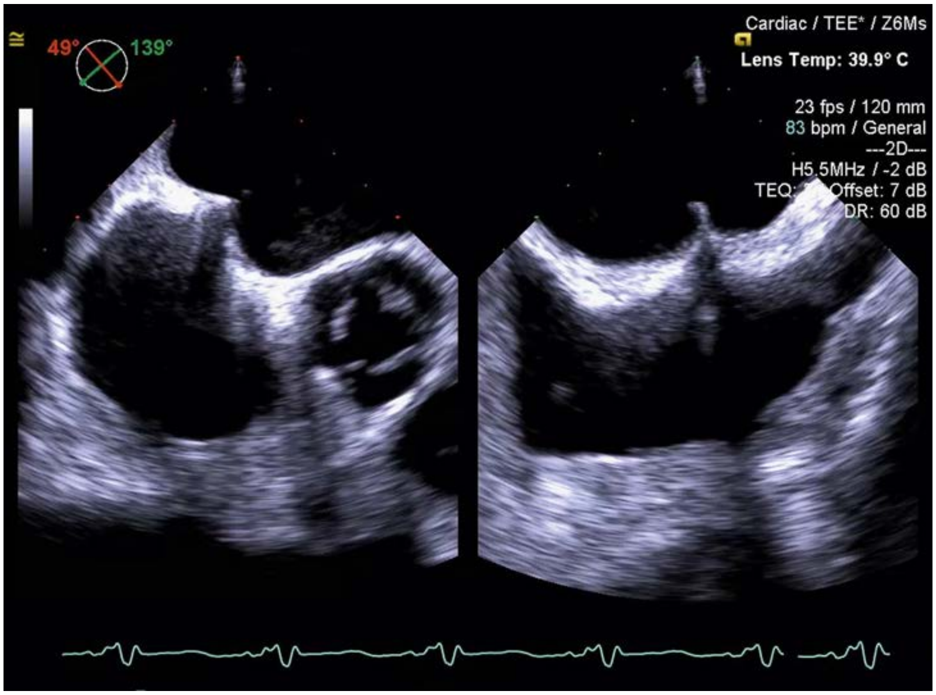

Fig. 37.29 Biplane imaging of modified midesophageal aortic valve short axis *(left)* and bicaval *(right)* views. Live biplane imaging is an essential tool in guiding puncture of the interatrial septum in catheter-based procedures entering the left side of the heart.

are based on the EVEREST study inclusion and exclusion criteria, and include regurgitation central in origin (A2/P2), lack of calcification in grasping area, mitral valve area greater than 4 cm^2, small flail gap (<10 mm), and narrow flail width (<15 mm).[227] Intraprocedural TEE, in combination with fluoroscopy, guides interatrial septal puncture and advancement of the catheter into the LA (Fig. 37.29). Under TEE guidance, the clip is aligned above the leaflets with the arms perpendicular to the line of coaptation. Once satisfactory position is obtained, the device system is advanced into the left ventricle (Fig. 37.30). Live echocardiographic imaging is often utilized as the system is slightly withdrawn so the clip grasps the leaflets; confirmation of bileaflet capture and assessment of the regurgitation severity is performed prior to clip deployment. Presence of significant residual or worsened MR, or evidence of mitral stenosis by echocardiography may prompt repositioning of the clip. Regurgitation and stenosis are quantified after deployment; placement of a second clip may be indicated if significant MR remains.

OTHER PERCUTANEOUS STRUCTURAL HEART PROCEDURES

TEE serves as a standard imaging modality in numerous other catheter-based procedures, including atrial septal defect closures, ventricular septal defect closures, LA appendage occlusion, valve-in-valve therapies for failed prostheses, and paravalvular leak closures. Echocardiography during these procedures assesses the suitability of the intervention, provides real-time guidance, and assesses the effectiveness of the intervention. Transcatheter techniques under investigation include mitral valve replacement[228] and therapies directed at TR, including valve annuloplasty, techniques targeting leaflet coaptation, and caval valve implantation.[229,230]

Emerging Technologies

FUSION IMAGING

Multimodality imaging is essential for planning and execution of percutaneous structural heart procedures. Interventional cardiologists use echocardiographic and fluoroscopic data simultaneously to guide catheter manipulation and device deployment. Often these images are displayed on separate screens, which can provide challenges as the proceduralist must combine the information to reconstruct a mental 3-D representation of the structures. Fusion of echocardiographic and fluoroscopic images provides simultaneous visualization of catheter movements with cardiac structures. Currently a technology in development, the optimal applications will be better characterized in the coming years.[231,232]

THREE-DIMENSIONAL PRINTING

3-D models of valvular structures and complex congenital heart defects can be printed from echocardiographic and other imaging data sets. Visual and tactile interactions with the models allow for improved understanding of structural interactions and abnormalities. At present, 3-D printing in this context is most relevant as a training and simulation tool, but patient-specific models can be used to optimize preprocedural planning.[233] Model quality depends on the quality of the imaging data. High cost, long printing times, and lack of materials capable of replicating tissue structural properties limit perioperative applications of 3-D printing.[234]

ARTIFICIAL INTELLIGENCE/MACHINE LEARNING

Artificial intelligence and its subfield, machine learning, permeate everyday life. The quest to apply these

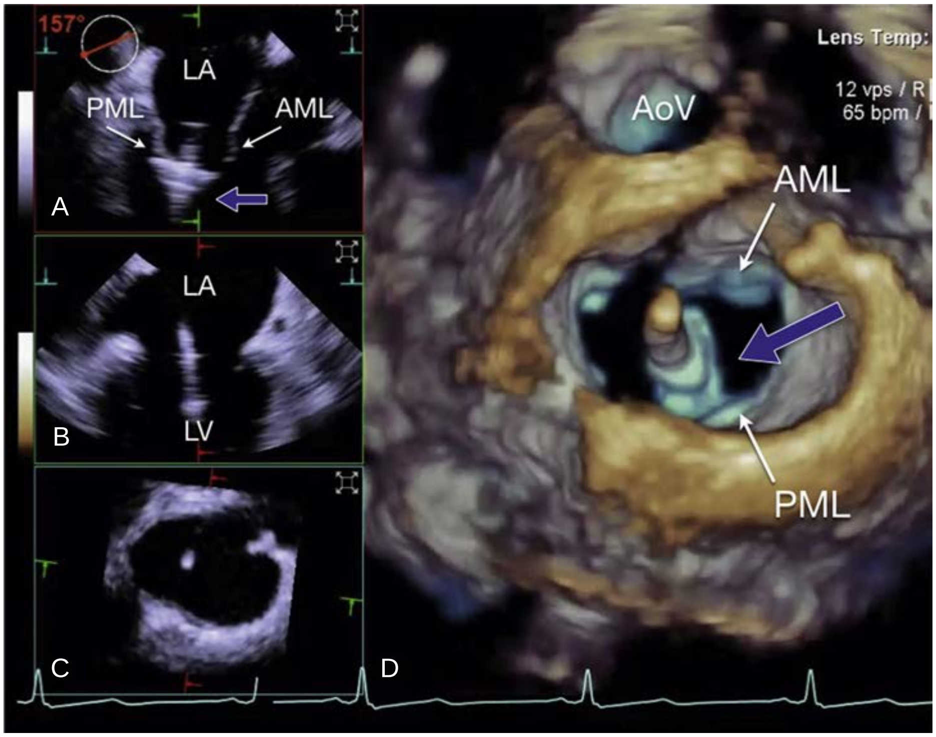

Fig. 37.30 Simultaneous live display of two-dimensional reference planes (Panels A-C) and the three-dimensional volume (Panel D) during a MitraClip procedure. The clip *(blue arrow)* should be aligned orthogonally to the line of coaptation of the mitral valve. Real-time imaging facilitates optimal device positioning by providing visual feedback following changes in catheter and device position. *AML*, Anterior mitral leaflet; *AoV*, aortic valve; *LA*, left atrium; *LV*, left ventricle; *PML*, posterior mitral leaflet.

technologies to questions in medicine is no exception. Artificial intelligence is a branch of computer science focused on development of computer systems capable of emulating human intelligence, including aspects such as learning, knowledge retention, problem solving, and reasoning.[235] Machine learning focuses on the development of predictive models where rules are learned from data rather than explicitly programmed.[236] Currently, many 3-D echocardiography platforms require manual, time-consuming user input for quantitative analysis, making their routine use in the operating room impractical. While not yet mainstream, automated analysis platforms using artificial intelligence in echocardiography exist, including mitral and aortic valve analysis in 3-D TEE[237] (Fig. 37.31) and automated chamber quantification in 3-D TTE.[238-240] Outside of the perioperative arena, machine learning has been applied to 2-D TTE assessment of LV hypertrophy phenotypes.[241] Refinement and continued development of such technologies conceivably could provide complex, quantitative valvular and ventricular analyses under dynamic conditions, improving accuracy and reducing inconsistencies in interpretation.

Perioperative Transthoracic Echocardiography and Focused Cardiac Ultrasound

While TEE has historically been the principal modality of perioperative echocardiography, TTE is emerging as a relevant and feasible counterpart. Anesthesiologists with substantial echocardiography experience have initiated preoperative TTE consult services, providing echocardiographic examination and interpretation when indicated during preoperative evaluation.[242-245] Echocardiographic findings have led to management changes in 54% to 84% of cases, including modification of the planned anesthetic approach and influencing decision making regarding the need for additional preoperative consultation or intraoperative monitoring.[242-244] Interpretation of the images by cardiologists[244] and formal TTE imaging in a subset of patients confirmed the major findings of the focused TTE examination in the majority of cases.[242,243] Standard preoperative echocardiography in patients undergoing major surgery has failed to demonstrate an association with improved outcomes,[246] so the value of preoperative anesthesiologist-performed TTE in guiding interventions or prognostication needs further characterization. As these consult services develop, important considerations include the intended scope of the examination and the experience of the individuals performing and interpreting the studies.

Several small investigations demonstrate the feasibility of FoCUS* prior to urgent or emergent surgical procedures, resulting in changes to the anesthetic technique or management plan.[247-249] Specific patient populations, such as patients sustaining hip fractures, may be optimally suited for FoCUS. Delay in surgery for hip fractures is associated with increased risk of mortality,[250,251] and preoperative echocardiographic examination through standard channels has been associated with delayed surgery.[252] A multi-center,

---

*These studies described the use of "focused transthoracic echocardiography." To maintain consistency with terminology proposed in published guidelines, we described these studies as FoCUS.

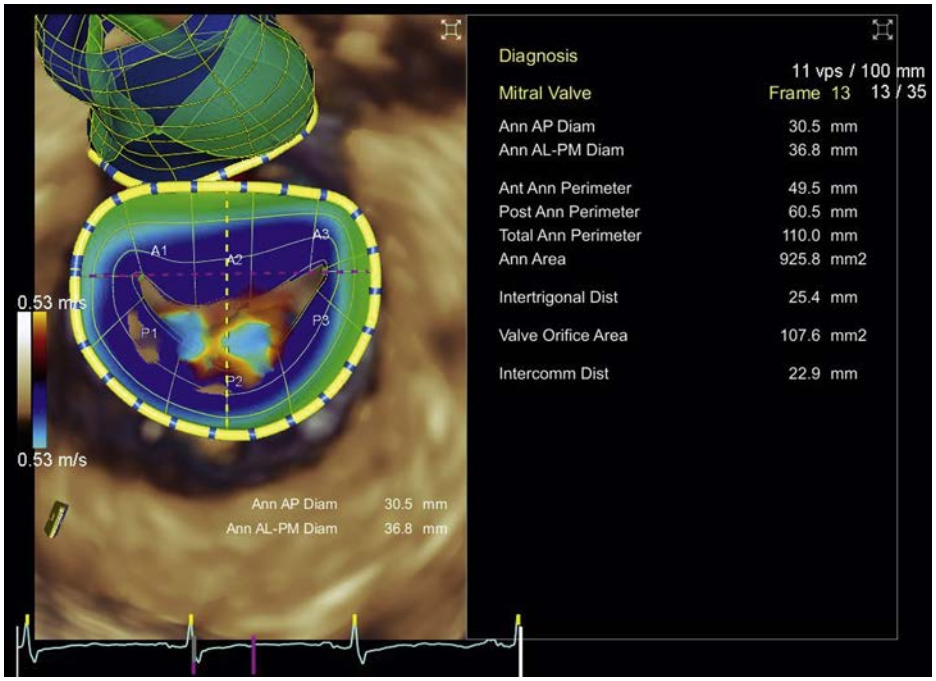

Fig. 37.31 Example of valve analysis program using artificial intelligence. Dynamic measurements of mitral annular geometry are provided throughout the cardiac cycle.

randomized pilot study of preoperative FoCUS in hip surgery has been completed, providing the groundwork for a larger, definitive randomized controlled trial.[253]

The operating theater, with the sterile surgical field and limited patient accessibility, is not necessarily conducive to transthoracic imaging. Despite the perceived challenges, small studies have prospectively demonstrated the feasibility of FoCUS during surgery. In a series that included stable and unstable patients undergoing a range of surgeries (orthopedics/trauma, abdominal/vascular, urology/gynecology, and head or ear, nose, and throat), focused examination was feasible in more than 90% of cases.[254] Patients with chronic obstructive pulmonary disease and those undergoing abdominal surgery had significantly worse image quality. Subsequent studies have demonstrated feasibility in thoracic surgery,[255] and an impact on intraoperative management in 22% to 66% of patients.[255,256]

There is increasing interest in FoCUS and TTE for hemodynamic monitoring and diagnostic assessments in the peripartum anesthetic management of pregnant women.[257] The leftward displacement of the heart and left tilt to avoid aortocaval compression are favorable for parasternal and apical imaging windows.[257] Postpartum hemorrhage, preeclampsia, and cardiomyopathy can all result in hemodynamic derangements detectable by cardiac ultrasound.[258]

Despite the recognized value of FoCUS,[259] it is not yet a routine aspect of anesthesiology practice. A survey of cardiothoracic anesthesiologists revealed a familiarity with FoCUS (81%), but only 47% of respondents use it in their clinical practice.[260] While the study has limitations, including low response rate, it provides insight into current practice patterns. The most frequently cited obstacle to use of FoCUS was lack of training, followed by concerns about missed diagnosis, lack of equipment, and lack of a certification process. As the majority of these anesthesiologists had prior formal echocardiography training (TEE, TTE, or FoCUS), it is likely the obstacles would be further amplified for anesthesiologists without this exposure.

Critical Care

Echocardiography performed and interpreted at the point of care is feasible and influential in the care of critically ill surgical and nonsurgical patients. Both TTE and TEE findings impact the management of patients in shock, influence diagnostic and therapeutic management,[261-263] and provide prognostic information.[264,265] In a study of 110 patients in undifferentiated shock, early resuscitation guided by echocardiography was associated with improved survival, less fluid administration, and greater inotrope use compared to 110 control patients examined retrospectively.[266] Although this does not indicate causality, it highlights the potential value of echocardiography in resuscitation, especially in light of the association between positive fluid balance and mortality.[267-269] TTE use is more prevalent than TEE in the ICU,[270] and European and Australian intensivists use TEE more commonly than their North American counterparts.[271] TEE offers improved diagnostic accuracy in the setting of mechanical ventilation,[261] however several groups have obtained adequate transthoracic images for focused studies in the majority of mechanically ventilated patients.[262,272,273] TEE provides superior imaging for the evaluation of suspected endocarditis or intracardiac mass, evaluation of great vessel pathology, and assessment of valvular dysfunction.[56]

Similar to perioperative TEE, there are proposed basic and advanced applications of critical care echocardiography.[54,57] Basic applications include assessment of global biventricular size and function, identification of pericardial fluid or tamponade, identification of severe valvular regurgitation, and as guidance for resuscitative efforts during and after cardiac arrest. Advanced applications include quantitative assessments of function and filling pressures, evaluation of fluid responsiveness, and detection of abnormalities including cardiac source of embolism, endocarditis, acute aortic pathology or injury, intracardiac shunt, and complications of MI. Evaluation of suspected endocarditis, great vessel pathology or injury, and PE may be considered basic or advanced applications.

FLUID RESPONSIVENESS

When assessing a patient in shock, the decision to administer, withhold, or stop fluids is often challenging. Patients who are fluid responsive will demonstrate an increase in SV or cardiac output in response to a fluid challenge,[107] and dynamic indices (such as heart-lung interactions or the passive leg raise maneuver) temporarily induce changes in preload to assess for this response. In patients receiving passive mechanical ventilation, several echocardiographic dynamic parameters have been used to predict fluid responsiveness and aid in clinical decision making:

- *Inferior vena cava distensibility index:* During positive pressure ventilation, inspiration causes a rise in intrathoracic pressure, which decreases the venous return to the heart and leads to IVC distension. During expiration, IVC diameter is at a minimum. Two IVC distensibility indices (dIVC or ΔIVC) relating the maximum ($D_{\max}$) and minimum ($D_{\min}$) diameters during the respiratory cycle have been described:

$$\Delta \text{IVC} = \frac{D_{\max} - D_{\min}}{D_{\min}} * 100\,\%$$

  where a threshold of 18% or greater discriminated between responders and nonresponders,[274]

  and

$$\Delta \text{IVC} = \frac{D_{\max} - D_{\min}}{(D_{\max} + D_{\min})\,/2} * 100\,\%$$

  where a threshold of 12% or greater discriminated between responders and nonresponders.[275]

  Use of the first equation is most common.[276] In more heterogeneous populations, ΔIVC performs less accurately (two subsequent studies report an area under the receiver operating characteristic curve of 0.43 and 0.635, respectively).[277,278] The reported optimal thresholds for discriminating responders from nonresponders also vary. In general, ΔIVC has greater specificity than sensitivity.

  Several preconditions must be met for ΔIVC to be a useful tool, including absence of spontaneous respiratory effort, 8 to 12 mL/kg tidal volumes (necessary to increase the pleural pressure to affect the IVC diameter), absence of cor pulmonale, and absence of intraabdominal hypertension.[108] Highlighting the importance of these conditions, ΔIVC accurately predicts fluid responsiveness in patients ventilated with tidal volumes of 8 to 10 mL/kg and PEEP of 5 cm H_2O or less but poorly predicts fluid responsiveness in patients receiving tidal volumes less than 8 mL/kg or PEEP greater than 5 cm H_2O.[276]

- *Superior vena cava collapsibility index:* During positive pressure ventilation, the SVC collapses during inspiration due to increased intrathoracic pressure (a pattern opposite that of the IVC). An initial study of patients with septic shock evaluated the SVC collapsibility index (ΔSVC), defined as:

$$\Delta \text{SVC} = \frac{D_{\max} - D_{\min}}{D_{\max}} * 100\,\%$$

  where $D_{\max}$ is the maximum diameter on expiration and $D_{\min}$ is the minimum diameter on inspiration.[279] A threshold of more than 36% distinguished fluid responders from nonresponders with 90% sensitivity and 100% specificity. In a larger cohort including mechanically ventilated patients with any type of shock, ΔSVC of 21% or greater predicted fluid responsiveness with 61% sensitivity and 84% specificity.[278] When compared in the same patients, ΔSVC has greater diagnostic accuracy than ΔIVC_1.[277,278] TEE imaging is required to determine ΔSVC.
- *Variation in peak aortic/LVOT velocity:* Positive pressure ventilation results in cyclical changes in the maximum velocity of flow in the LVOT and across the aortic valve. Application of PWD at the level of the aortic valve[280] or in the LVOT[278] allows for measurement of the highest (V_{max}) and lowest (V_{min}) peak velocities over the course of the respiratory cycle. The difference between the two is divided by their mean and expressed as a percentage as follows:

$$\Delta V_{\max}\text{Ao} = \frac{V_{\max} - V_{\min}}{(V_{\max} + V_{\min})\,/2} * 100\,\%$$

  A threshold of 12% or more discriminated between responders and nonresponders in initial investigations.[280] Similar to other dynamic indices, in larger, diverse populations, this parameter does not perform as accurately as originally reported. When compared in the same cohort, $\Delta V_{\max}\text{Ao}$ had the highest sensitivity, whereas ΔSVC had the highest specificity for predicting fluid responsiveness.[278]

Additional echocardiographic assessments utilizing heart-lung interactions and dynamic parameters are an area of active research. End-expiratory occlusion maneuvers alone or in combination with end-inspiratory occlusions have been used to predict fluid responsiveness as assessed by changes in LVOT velocity time integral and/or maximum aortic velocity.[281,282] These approaches are not currently widely applied and require further validation in varying patient populations. With any of these indices, the clinician should interpret these findings within the overall context of the patient's status and with an awareness of the limitations.

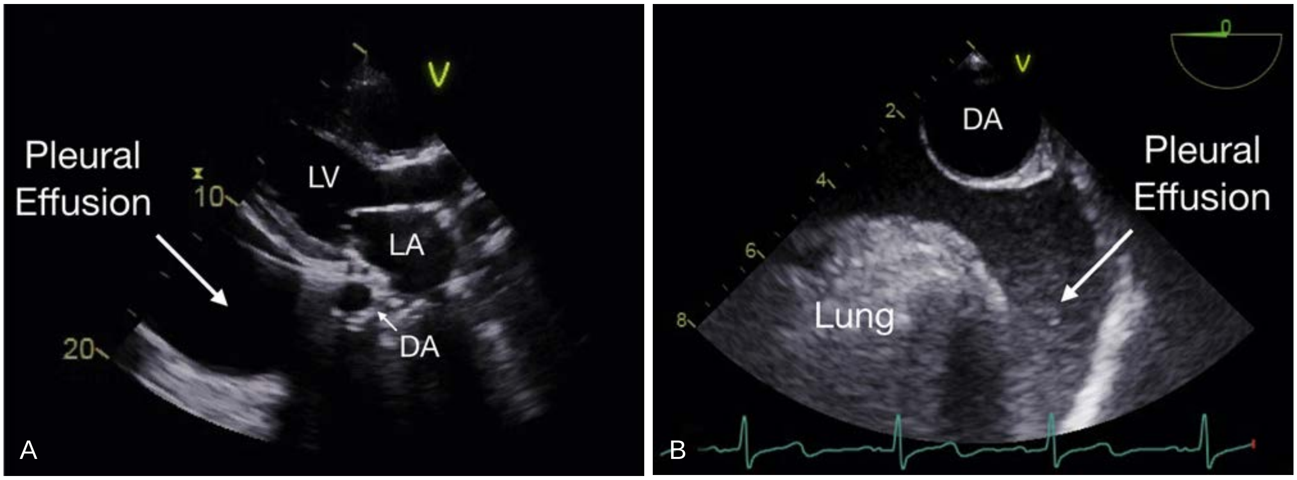

Fig. 37.32 Pleural effusions demonstrated by echocardiography. (A) This transthoracic parasternal long axis view demonstrates an echolucent space posterior to the DA, consistent with a large left pleural effusion. A pericardial effusion (not present in this image) would be seen as an echolucent space anterior to the descending aorta. (B) A transesophageal descending aorta short axis view demonstrating an echolucent space consistent with a left pleural effusion. Note the atelectatic lung at the left of the image. *DA,* Descending aorta; *LA,* left atrium; *LV,* left ventricle.

POST-CARDIAC SURGERY

A 2016 systematic review of 15 studies examining TTE and TEE after cardiac surgery demonstrated that echocardiography (performed by a mix of novice and expert sonographers) was feasible and that findings frequently led to management changes.[283] In hemodynamically unstable postoperative cardiac surgical patients, significant discordance has been demonstrated between diagnoses obtained from continuous TEE and diagnoses obtained from hemodynamic measurements.[284] TEE-based diagnoses have greater interobserver agreement, suggesting that echocardiography may add valuable diagnostic information even in the presence of invasive hemodynamic monitors.

TRAUMA AND RESUSCITATION

For decades, cardiac ultrasound via the subcostal window has been part of the evaluation of the trauma patient within the Focused Assessment with Sonography for Trauma (FAST) examination.[285] FoCUS extends this cardiac examination and has been adopted as a tool to guide resuscitation of trauma patients. A trial randomizing trauma patients to FoCUS or no FoCUS as part of the initial evaluation demonstrated significantly less fluid administration, shorter time from the trauma bay to the operating room, and higher rate of ICU admissions in the FoCUS group.[286] In blunt or penetrating chest trauma, echocardiography reveals complications such as cardiac rupture, dysfunction (due to contusion), valvular injury, hemopericardium, and aortic disruption.[287]

OTHER CLINICAL APPLICATIONS

Echocardiography may identify causes of hypoxia, such as right-to-left intracardiac shunt or pleural effusion (Fig. 37.32). Clinicians often incorporate lung ultrasound with echocardiography when evaluating cardiopulmonary failure (also see Chapter 83).[288]

Novel applications of echocardiography in critical care are emerging. Areas of active research include strain imaging in sepsis[289] and the use of echocardiography in evaluating patients that fail to liberate from mechanical ventilation.[290]

HANDHELD CARDIAC ULTRASOUND

With their compact size and portability, handheld echocardiography devices are ideal for point-of-care assessments.[291] Intensivists with limited echocardiography training have performed and interpreted focused handheld examinations, estimating LV systolic function with reasonable accuracy compared to formal TTE performed by a sonographer and interpreted by an echocardiographer.[292] When performed by intensivists experienced in echocardiography, handheld echocardiographic examinations offer similar 2-D diagnostic capabilities to full-platform TTE in mechanically ventilated, critically ill patients, with limitations due to lack of spectral Doppler.[293]

MINIATURE TEE PROBES

Miniature TEE probes have promise as tools for hemodynamic monitoring or characterization of cardiopulmonary failure in the critical care setting.[294,295] Examination with miniaturized multiplane TEE probes is feasible and well tolerated in ventilated, critically ill patients.[295] When compared to standard TEE, miniature probes enable concordant diagnostic assessments of causes of cardiorespiratory failure, albeit with lesser image quality. Consequent to the diminished image quality, common hemodynamic measurements can be performed less frequently, but when possible, the results agree with those obtained by standard TEE. Larger studies and evaluation of resulting clinical impact are necessary prior to widespread adoption of miniature TEE.

Training and Certification

KNOWLEDGE EXPECTATIONS AND TRAINING

Across the field of anesthesiology, there is a growing impetus for formalized training in perioperative ultrasound including echocardiography. The American Council for Graduate Medical Education requires anesthesiology residents to demonstrate competency in the acquisition of standard transesophageal and transthoracic echocardiographic views.[296] Certification by the American Board of Anesthesiology requires basic knowledge of TEE, assessed both in the written examination[297] and the Objective Structured Clinical Exam.[298] Accredited Anesthesiology Critical Care Medicine programs require fellows to demonstrate knowledge of ultrasound principles and proficiency in TEE and TTE.[299]

Formalized echocardiography training requires curriculum development and educational initiatives. For some trainees, exposure to ultrasound now begins in medical school. Several institutions include cardiac ultrasound in their educational programs, initially using it to teach anatomy and function, and later as an adjunct to the physical examination.[300] Many residency programs are developing multimodal longitudinal curricula including didactic lectures, hands-on workshops, online modules, simulation, and formal echocardiography rotations.[301-304] Online virtual simulation provides users an interactive format to learn standard views and spatial relationships.[305,306] Mannequin-based simulation is an effective method for improving the acquisition of cognitive and technical skills both in TEE[307-312] and TTE,[308,313,314] and may be a useful educational tool for learners early in training. In addition to these multimodal didactic approaches, practical clinical experience under supervision remains a key part of the training process. In North America, advanced training in TEE usually occurs in the context of the cardiothoracic anesthesiology fellowship.

The coming years will likely include increasing emphasis on FoCUS training in anesthesiology. In a survey of US anesthesiology residency program directors and trainees, the majority of respondents indicated FoCUS should be a standard component of training, while only a minority of the programs incorporated such training.[315] A different survey of Canadian residency program directors indicated FoCUS training should be compulsory, and while most of the programs had training opportunities, only a minority included mandatory rotations.[316] The challenge to the specialty is how to best incorporate FoCUS, to define minimum training standards and competencies, and to provide education for trainees as well as anesthesiologists already in practice. The European Association of Cardiovascular Imaging has published a reference curriculum and syllabus for FoCUS education and training.[317] Clinicians must clearly understand the narrow scope of FoCUS, recognizing the limitations and indications for expert consultation. Many examples of the applicability of perioperative FoCUS are in the hands of experienced echocardiographers—whether this translates to operators with less experience and less formal training will need to be examined. After the initial acquisition of cognitive and technical skills in ultrasound, continued use is important to ensure proficiency; when these skills are not used for over a year, significant attrition occurs.[318]

CERTIFICATION

The National Board of Echocardiography offers examination and certification in basic (Basic PTEeXAM) and advanced (Advanced PTEeXAM) perioperative TEE.[319] Individuals that pass the examination achieve testamur status. Testamurs can achieve basic certification via supervised training, practice experience, or extended continuing medical education. Advanced PTEeXAM testamurs can receive certification by completing an accredited cardiothoracic anesthesiology pathway; a practice experience pathway is only available to individuals that completed training prior to 2009. There is no certification for perioperative TTE, however, qualified individuals can take the Examination of Special Competence in Adult Comprehensive Echocardiography (ASCeXAM) and achieve testamur status. In Europe, the European Association of Cardiovascular Imaging and European Association of Cardiothoracic Anaesthesiology jointly offer certification in adult TEE.[320] General critical care ultrasound and basic critical care echocardiography are now considered to be within the scope of practice of intensivists, while certification has been proposed for those obtaining advanced training.[55,56] As of 2019, the National Board of Echocardiography now offers an Examination of Special Competence in Critical Care Echocardiography (CCEeXAM).[321]

Future Directions

The evolution of perioperative echocardiography is at a transformative juncture. The landscape is one of growth, innovation, and accessibility. From its perioperative origin as a monitor in cardiac surgery decades ago, TEE has become integral to the practice of cardiac anesthesia and surgical decision making. More sophisticated and automated platforms will pave the way for increasingly complex, quantitative analyses to be performed in real time. Catheter-based procedures push the boundaries of treatable pathologies, and echocardiography is central to the multimodal imaging techniques employed by structural heart teams. Many cardiac anesthesiologists have an interest in TTE, which complements and builds upon their already established cognitive and technical skills.

Outside of the cardiac arena, anesthesiologists use TEE as an intraoperative monitor in high-risk procedures or populations. Basic knowledge of TEE is now expected of anesthesiology trainees. In the future, knowledge of transthoracic imaging in the form of FoCUS may too become a requirement. Increased portability of ultrasound machines and newer technologies like capacitive micromachined ultrasound transducers make the potential for widespread point-of-care imaging an imminent reality. With the growing interest and investment in ultrasonography, a basic skill set may soon be within the purview of all anesthesiologists. Opportunities for research into education and the impact of anesthesiologist-performed examinations abound. Critical care training objectives now include basic proficiency in echocardiography in the larger context of critical care ultrasound. Similar to advanced perioperative TEE, proficiency in advanced critical care echocardiography requires additional dedicated training and allows comprehensive evaluation of cardiac structure and function, and hemodynamic assessments in the context of the critically ill patient. Whether applied as a routine monitor, a more advanced diagnostic tool, or used in procedural guidance, echocardiography is an essential component of the modern perioperative physician's armamentarium.

Acknowledgment

The editors and publisher would like to thank Drs. Georges Desjardins, Daniel P. Vezina, Ken B. Johnson and Michael K. Cahalan for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Video 37.1 **3D Imaging—multiple beat full-volume acquisition.** Multiple beat full-volume acquisitions create three-dimensional images by acquiring individual data subvolumes over consecutive heartbeats and then "stitching" the data together to create the larger full-volume image.

Video 37.2 **Echocardiographic views in focused cardiac ultrasound (FoCUS):** Parasternal long axis (PLAX), parasternal short axis (PSAX), apical four-chamber (A4C), subcostal four-chamber (SC4), and subcostal IVC (SIVC). *A,* Anterior wall; *AML,* anterior mitral leaflet; *AoV,* aortic valve; *DA*, descending aorta; *I,* inferior wall; *IVC*, inferior vena cava; *IVS,* interventricular septum; *L,* lateral wall; *LA,* left atrium; *LV,* left ventricle; *PML,* posterior mitral leaflet; *RA,* right atrium; *RV*, right ventricle; *RVOT,* right ventricular outflow tract; *S,* septal wall.

Video 37.3 Transesophageal echocardiographic views demonstrating qualitatively normal left ventricular systolic function. *AoV,* Aortic valve; *LA,* left atrium; *LV,* left ventricle; *MV*, mitral valve; *RA,* right atrium; *RV,* right ventricle.

Video 37.4 Transthoracic parasternal short axis view demonstrating flattening of the interventricular septum in *diastole,* a finding observed in states of right ventricular volume overload. The septal curvature remains normal and the left ventricular cavity appears circular during systole. Of note, both left and right ventricular systolic function are reduced. *IVS,* interventricular septum; *LV*, left ventricle; *RV,* right ventricle.

Video 37.5 Transthoracic parasternal short axis view of a patient with right ventricular pressure overload. The leftward shift and flattening of interventricular septum occurs throughout the cardiac cycle, but is most pronounced at *end-systole. IVS,* Interventricular septum; *LV*, left ventricle; *RV,* right ventricle.

Video 37.6 **Takotsubo cardiomyopathy.** These clips demonstrate the classic pattern of apical ballooning with preserved basal contractility seen in Takotsubo (stress-induced) cardiomyopathy. Additional patterns of regional involvement may also be observed.

Video 37.7 **Systolic anterior motion of the mitral valve (SAM).** The anterior mitral leaflet is visualized entering the left ventricular outflow tract and contacting the interventricular septum during systole. Turbulent flow is visualized in the left ventricular outflow tract (LVOT) and significant mitral regurgitation (MR) is present. Treatment of SAM includes discontinuation (or avoidance) of inotropes, increasing preload, increasing afterload, and decreasing the heart rate. With therapeutic interventions, the SAM decreases, there is less turbulence in the LVOT, and the MR decreases.

Video 37.8 **Tamponade-right atrial systolic collapse.** A large echolucent pericardial effusion is demonstrated (*). Within the effusion, there are areas of increased density suggesting organization. Right atrial collapse *(blue arrow)* during ventricular systole supports the clinical diagnosis of tamponade. *LA,* Left atrium; *LV*, left ventricle; *RA,* right atrium; *RV,* right ventricle.

Video 37.9 **Tamponade-right ventricular diastolic collapse.** Transthoracic parasternal long axis views displaying a large pericardial effusion (*). Right ventricular diastolic collapse *(green arrow)* is present, and supports the clinical diagnosis of tamponade. Left atrial collapse during ventricular systole, often observed later than right-sided chamber collapse, is also present *(red arrow). Ao,* Ascending aorta; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *RVOT,* right ventricular outflow tract.

Video 37.10 McConnell's sign is an echocardiographic finding of right ventricular hypokinesis or akinesis with apical sparing. The apparent preservation of apical contractility actually reflects translational motion due to tethering of the apical fibers to the left ventricle. McConnell's sign may be observed in acute pulmonary embolism or right ventricular infarction. *IVS,* Interventricular septum; *RA,* right atrium; *RV,* right ventricle.

Implantable Cardiac Pulse Generators: Pacemakers and Cardioverter-Defibrillators

AMAN MAHAJAN and JACQUES PRINCE NEELANKAVIL

KEY POINTS[a]

- Identify the type of cardiovascular implantable electronic device (CIED) (pacemaker, transvenous defibrillator, subcutaneous defibrillator), as well as the generator manufacturer and model of the CIED.
- Contact the physician or clinic managing the patient's CIED in the preoperative period to obtain appropriate records and a perioperative recommendation (Heart Rhythm Society [HRS]).
- Obtain a copy of this interrogation and the perioperative recommendation from the CIED physician (HRS). Ensure that the implantable cardioverter-defibrillator (ICD) treatment settings are appropriate and that the CIED will pace the heart.
- Consider replacing any CIED near its elective replacement period in a patient scheduled to undergo either a major surgical procedure or a surgical procedure where monopolar electrosurgery will be used within 15 cm of the generator.
- Determine the patient's underlying rate and rhythm to determine the need for backup (external) pacing support.
- Ensure that all magnet behavior (pacing, suspension of shock therapy) is appropriate if magnet use is planned.
- Program minute ventilation rate responsiveness "off," if present.
- Consider disabling all rate enhancements to prevent misinterpretation of cardiac rhythm.
- Consider increasing the lower rate limit to provide optimal oxygen delivery for major procedures.
- If electromagnetic interference is likely, (1) disable antitachycardia therapy if a defibrillator is present and (2) consider asynchronous pacing for some pacing-dependent patients. Magnet application may be acceptable for some ICDs (disable antitachycardia therapy) or pacemakers (provide asynchronous pacing). Asynchronous pacing from an ICD always requires reprogramming.
- Monitor cardiac rhythm with the pulse oximeter (plethysmography) or arterial waveform analysis.
- Use a bipolar electrosurgical unit (ESU), if possible; if not possible, then pure "cut" electrosurgery is better than "blend" or "coag," and ESU should be applied in short bursts (<4 seconds) separated by at least 2 seconds.
- Place the ESU dispersive electrode in such a way to prevent electricity from crossing the generator-heart circuit.
- If the ESU causes ventricular oversensing with pacing quiescence or atrial oversensing with inappropriate ventricular pacing, limit the effect by using short ESU bursts, relocating the dispersive electrode, or placing a magnet over the pacemaker (not indicated for ICDs).
- Some patients require postoperative interrogation, especially if preoperative reprogramming took place. For "low-risk cases," HRS (but not ASA) states that this interrogation can take place in an ambulatory setting up to 1 month postoperatively. Some rate enhancements can be reinitiated, and a determination of optimum heart rate and pacing parameters should be made. Any patient with disabled antitachycardia therapy must be monitored until the antitachycardia therapy is restored.

---

[a] Adapted from the American Society of Anesthesiologists (ASA) *Practice Advisory* (2005, revised 2011) and the Heart Rhythm Society (HRS), formerly the North American Society of Pacing and Electrophysiology (NASPE) and ASA *Consensus Statement* (2011) *for Perioperative Management of Patients With a Pacemaker or Defibrillator.*

Introduction

Cardiac implantable electronic devices (CIEDs) refer to a permanently implanted cardiac pacemaker, an implantable cardioverter-defibrillator (ICD), or a cardiac resynchronization therapy (CRT) device. Evolving technology for CIEDs and their widespread use for bradyarrhythmias, tachyarrhythmias, and congestive heart failure management have made the perioperative management of these devices critical for anesthesiologists. It is estimated that more than 3 million people in the United States have a pacemaker and more than 300,000 people have an ICD.[1,2] With approximately 1 million patients worldwide receiving a pacemaker or ICD every year, patients with CIEDs are a growing population in the perioperative arena. The prevalence of cardiovascular disease in an aging population is an important driver for the increased utilization of CIEDs.

Historically, there was little guidance for anesthesiologists caring for patients with CIEDs because of the conflicting consensus statements regarding the perioperative management of CIEDs. In 2011, the Heart Rhythm Society (HRS)/American Society of Anesthesiologists (ASA) published an Expert Consensus Statement on the perioperative management of patients with CIEDs. This statement was in collaboration with the American Heart Association (AHA) and the Society of Thoracic Surgeons (STS).[3] This article provides information and a guided team approach to best manage this patient population, and it has become an important piece of literature for anesthesiologists. In this chapter, we will review basic CIED function, the perioperative management of these devices, and emerging technology of CIEDs.

Basic Cardiac Implantable Electronic Device Function

PACEMAKERS

Pacemakers are devices placed for bradyarrhythmias, and they remain the only effective treatment for ameliorating symptomatic bradycardia due to sinus node dysfunction (e.g., sick sinus syndrome) or a failure of impulse propagation (e.g., complete heart block). Advances in technology and understanding of cardiac conduction physiology have led to the development of more physiologic pacing. Pacemakers have become sophisticated at maintaining the normal atrial-ventricular activation over various heart rate ranges, varying the heart rate in response to metabolic demands, and preserving natural ventricular activation. Pacemakers have many additional features that correspond to the changing needs of patients throughout the day, including rate responsiveness to increase pacing during times of increased physical exertion and sleep functions to decrease pacing rate during times of rest. Standard pacemakers have either one or two (atrial and ventricular) leads. A patient is considered to be pacemaker dependent if they suffer significant symptoms or even cardiac arrest upon the cessation of pacing.[4,5]

The dual chamber pacemakers are capable of pacing and sensing in both the ventricle and the atrium. Such capability permits the pacemaker to ensure not only an adequate ventricular rate, but to preserve the atrial contraction before each ventricular contraction. These pacemakers guarantee a minimum atrial rate and also ensure that a ventricular contraction occurs within a specified amount of time after each atrial contraction. Limitations on ventricular rate are usually built in the circuitry and are programmable. Most pacemakers have the capability of varying the pacing rate. In the rate adaptive mode, the pacemakers sense the patient's level of activity and accordingly adjust the pacing rate using sensors that are typically piezoelectric and detect body motion transmitted from underlying muscles. Another method of determining the presence of physical activity utilizes detection of the respiratory rate and/or volume using bioimpedance sensors.

All pacemakers generate a pulse of current to depolarize a small region of the myocardium; the wave then spontaneously spreads to the rest of the myocardium. The pacing capture threshold is the minimum electrical energy needed to consistently capture the heart outside of the refractory period and is determined by (1) the intrinsic excitability of the myocardium, (2) the current density at the electrode-tissue interface, and (3) the duration of the electric pulse.

The North American Society of Pacing and Electrophysiology (NASPE) and the British Pacing and Electrophysiology Group (BPEG) initially published a generic pacemaker code (NBG code) in 1987. In 2002 the NBG code was subsequently revised (Table 38.1).[6] Common perioperative pacing modes include dual chamber, adaptive-rate pacing (DDDR), dual chamber pacing without atrium synchronous ventricular pacing (DDIR), and dual chamber asynchronous pacing with no rate modulation or multisite pacing (DOO).

1. DDDR pacing defines a pacemaker programmed to pace the atrium and/or ventricle, sense the atrium and/or ventricle, inhibit or trigger pacing output in response to a sensed event, and have a rate responsive sensor that is able to alter paced rates due to changes in perceived metabolic demand. DDDR is a very common program configuration for patients with sick sinus syndrome and/or heart block.

TABLE 38.1 2002 NASPE/BPEG Generic Code for Antibradycardic Pacing

Position	I	II	III	IV	V
Description	Chamber Paced	Chamber Sensed	Response to Sensing	Rate Modulation	Multisite Pacing
Possible designations	D = Dual (A+V) A = Atrium V = Ventricle O = None	D = Dual (A+V) A = Atrium V = Ventricle O = None	D = Dual (T+I) T = Triggered I = Inhibited O = None	R = rate modulation O = None	D = Dual (A+V) A = Atrium V = Ventricle O = None

2. DDIR is a common pacing mode for patients with supraventricular tachyarrhythmias (SVTs). If a patient is set to DDD, the ventricle response depends on the atrial rate. During SVT in DDD mode, rapid ventricular pacing may occur. In DDI, the pacemaker paces and senses both the atrium and ventricle; however, the device will not pace the ventricle at an identical rate if the patient has SVT. The response to a fast rate in the atrium will lead to inhibition of pacing in the ventricle—hence the *I* in the third designation. Most modern pacemakers have built-in automatic mode switching during episodes of SVT. They will switch from DDD to DDI to avoid SVT with a rapid ventricular response.
3. For some perioperative care, devices will be placed in an asynchronous mode like DOO. An asynchronous mode or nontracking mode will pace the atrium and ventricle at a set rate, regardless of the underlying rate and rhythm. This is advantageous in the perioperative environment in order to avoid the pacemaker from oversensing the monopolar electrocautery as intrinsic cardiac conduction. Asynchronous modes avoid oversensing (and under pacing) hearts that are pacemaker dependent and inhibited from pacing due to monopolar electrocautery (Table 38.2).

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

ICDs are implanted in patients for primary or secondary prevention of cardiac arrest. Primary prevention refers to ICD placement for patients who have not had any episodes of ventricular arrhythmias but who are at risk for future events. Secondary prevention refers to ICD placement for patients who have had prior ventricular arrhythmias. There is strong evidence that ICDs implanted for primary prevention improve mortality in high-risk patients, including patients with a left ventricular ejection fraction less than 40% who are on optimal medical therapy.[7-11] For patients with ischemic and nonischemic cardiomyopathy, ICDs reduce mortality approximately 23% to 55%.[12,13] Certain groups of patients do not benefit from ICD implantation, including patients with recent myocardial infarction and patients who have received coronary artery bypass grafting.[14] In addition, many of the patients in the decisive trials for ICD placement were younger (mean or median age between 58 and 67 years for the MADIT-II, CABG-PATCH, DINAMIT), whereas many patients currently receiving ICDs are over the age of 70.[15]

ICDs have four main functions. They sense atrial or ventricular electrical activity, classify these signals to various programmed "heart rate zones," deliver tiered therapies to terminate ventricular tachycardia (VT) or fibrillation, and pace for bradycardia. All modern ICDs are pacemakers, and this has important perioperative applications. Although ICDs improve survival in many patients, unnecessary shocks are very detrimental. They are proarrhythmic, can lead to anxiety and depression, and decrease patient quality of life. Inappropriate shocks are common (30% to 50% of all shocks) as a result of inappropriate treatment of SVT, oversensing physiologic T waves, or lead fracture.[16] The discrimination between VT and SVT is critical for ICDs to avoid inappropriate therapy. There are several methods by which ICDs discriminate between SVT and VT. Single chamber ventricular ICDs utilize ventricular–ventricular timing intervals and QRS morphology. Dual chamber ICDs use atrial–atrial timing intervals and the chamber of onset. Subcutaneous ICDs assess surface electrocardiogram (ECG). The sensitivity and specificity for VT detection by QRS morphology is more than 90%.[16]

ICDs terminate ventricular arrhythmias by either antitachycardiac pacing (ATP) or defibrillation. ATP terminates reentrant VT by blocking reentry and it terminates slow VT (<188 to 200) approximately 90% of the time. ATP is desirable because it reduces inappropriate shocks and prolongs battery life. For VT that is not terminated by ATP or for ventricular fibrillation (VF), defibrillation is the treatment of choice. The energy for defibrillation may be incrementally increased or set to maximum energy for each shock.[17]

TABLE 38.2 Common Pacemaker Settings

Examples	Chamber Paced	Chamber Sensed	Response to Sensing	Rate Modulation	Multisite Pacing	Common Clinical Utilization
AAI	Atrium	Atrium	Intrinsic atrial beat inhibits atrial pacing	None	None	Sick sinus syndrome with intact atrioventricular conduction
DDDR	Both	Both	Intrinsic beat will inhibit output; atrial beat will trigger ventricular pacing if lack of intrinsic ventricular beat	Present	None	Atrioventricular block
VVIRV	Ventricle	Ventricle	Intrinsic ventricular beat will inhibit ventricular pacing	Present	Multisite ventricular pacing	Heart failure with prolonged QRS
DOO	Both	None	None	None	None	Perioperative asynchronous setting to avoid electromagnetic interference

CARDIAC RESYNCHRONIZATION THERAPY DEVICES

CRT plays an important role in the management of heart failure and is becoming a device commonly encountered by anesthesiologists because of the large prevalence of heart failure in this country. These devices are indicated in select patients with heart failure, systolic dysfunction, and a prolonged QRS. Conduction abnormalities are frequently seen in systolic heart failure, with approximately 25% to 40% of these patients having a prolonged QRS complex (>120 ms).[18] In these patients, cardiac depolarization spreads slowly through the myocardium without a healthy Purkinje conduction system, leading to intraventricular dyssynchrony. During intraventricular dyssynchrony, the left ventricular (LV) septal wall contracts earlier than the lateral wall, which leads to less efficient ejection from the left ventricle in addition to decreased diastolic filling. The goal of CRT is to restore synchronous contraction of the left ventricle and to optimize timing of LV and right ventricular (RV) ejection. This is accomplished through biventricular pacing using a standard RV lead and an LV lead placed adjacent to the lateral wall via the coronary sinus. Biventricular pacing in the right ventricle and the left ventricle leads to improved hemodynamic variables, including systolic blood pressure, stroke volume, cardiac output, and rate of rise of LV pressure (dP/dt). In contrast to pharmacologic means of improving systolic function, CRT improves cardiac performance with reductions rather than with increases in myocardial metabolic demand. In addition, CRT has been shown to improve mitral regurgitation (MR) and New York Heart Association (NYHA) function class because of reverse ventricular remodeling over time.[19] Standard indications for CRT are LV ejection fraction (LVEF) less than 35% with QRS greater than 120 ms, sinus rhythm, and NYHA class III or IV after optimal medical therapy. Left bundle branch block is the most common conduction abnormality in patients undergoing CRT. Approximately 30% of patients meeting selection criteria for CRT do not respond to biventricular pacing. Risk factors for failure to respond to CRT include ischemic cardiomyopathy, sustained VT, severe MR, and dilated LV cavity.[20] CRT has been shown to reduce mortality, heart failure symptoms, and also heart failure hospitalizations. Patients with CRT should be considered pacemaker-dependent because of the constant pacing they undergo to synchronize the ventricle.

Perioperative Considerations

PREOPERATIVE ASSESSMENT

As perioperative physicians, the preoperative assessment of patients with CIEDs is critical to safe and time-efficient care. The key to the preoperative assessment is timely communication between the anesthesia provider and the CIED team that usually manages the device programming and function. The CIED team may include a cardiologist, an electrophysiologist, and/or a physician extender such as a nurse or nurse practitioner. The CIED team needs to know various information about the surgical case and postoperative disposition in order to create an individualized care plan for the patient. The anesthesiology provider must communicate the specifics of perioperative care to the CIED team in order to ensure a proper plan specific to that patient and the surgical case. Unfortunately, there is no single prescription for CIED management that can be applied to all patients coming for surgery. In addition, it is not recommended that an industry-employed allied profession determine the perioperative plan for a particular CIED.[21]

The perioperative team must convey to the CIED team important information regarding the presence of electromagnetic interference (EMI), the likelihood of cardioversion or defibrillation, patient position, location of surgery that may damage or encroach upon the CIED leads, and postoperative disposition. The CIED team must communicate with the anesthesiology team the date of last interrogation, the type of CIED device, the indication for CIED placement, the battery life, pacemaker dependence, and magnet response. Each of these vital perioperative parameters are discussed in detail in this chapter.

The goal of a thorough preoperative evaluation between the CIED and anesthesia teams is to avoid CIED complications in the perioperative period, such as damage to the device, inability of the device to deliver pacing or shocks, lead-tissue interface damage, changes in pacing behavior, electrical reset to the backup pacing mode, or inappropriate ICD therapies. Any of the these complications can lead to poor patient outcomes, including hypotension, arrhythmias, and myocardial ischemia.

PREOPERATIVE INFORMATION TRANSFER

The ACCF/AHA/HRS 2011 guidelines emphasize that a team approach should be utilized when caring for patients with CIEDs. Patients coming for surgery with CIEDs do not need routine interrogations prior to surgery unless there has been a change in clinical presentation. For patients with a pacemaker, they should have an interrogation report within the last 12 months; patients with an ICD or CRT should have a report within the previous 6 months. The different time courses for interrogations between pacemakers and ICDs and CRT devices reflect the overall cardiovascular comorbidities of these respective patient populations. By definition, patients with ICDs and CRT devices have decreased systolic function and heart failure, and they are more likely to have clinical decompensation compared to patients with isolated pacemakers. Worsening cardiovascular function might negatively impact CIED performance. The preoperative evaluation begins with general considerations, such as establishing whether a patient has a CIED and defining the type of device. A focused history and physical, including rhythm strips and ECGs, can usually answer important basic questions about the patient’s CIED. After these are completed, it is important to define the type of the device to be used. If the patient has been seen by the CIED team, they will leave a detailed note.

Within the interrogation report, it is important to note the type of device. Patients with pacemakers have different clinical risk profiles compared with those with ICDs and CRTs. In addition, the goals of perioperative management for these devices are different. Most pacemakers encourage intrinsic cardiac conduction because this maintains atrial–ventricular synchrony, LV-RV synchrony, and septal

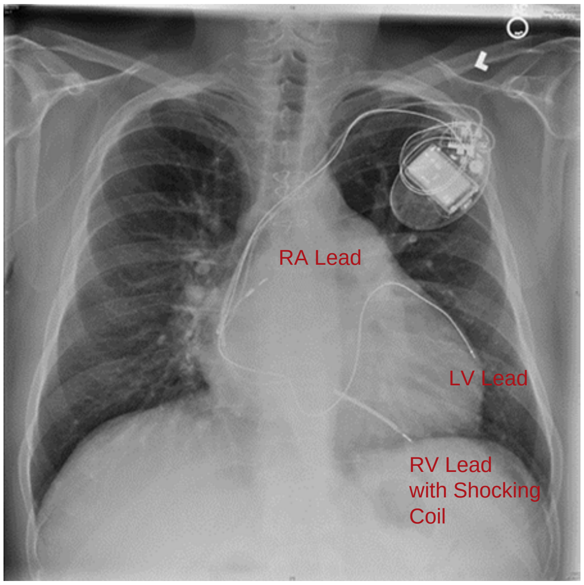

Fig. 38.1 Chest radiograph: the pulse generator is located in the left deltopectoral groove. There are three leads visualized: a lead in the right atrium *(RA)*, a lead in the left ventricle *(LV)* via the coronary sinus, and a lead in the right ventricle *(RV)*. The RV lead has a thicker diameter toward the tip, indicating it is an implantable cardioverter-defibrillator lead.

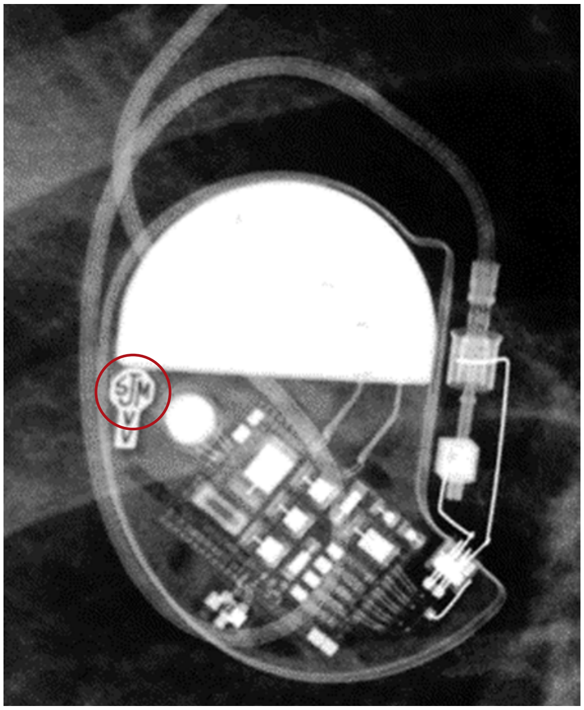

Fig. 38.2 Chest radiograph of the cardiovascular implantable electronic device generator. The letter designation on the generator allows the physician to identify this manufacturer as St. Jude Medical.

LV–lateral LV synchrony. Although DDD pacing of both atrium and ventricle in a dual-chamber pacemaker maintains atrioventricular (AV) synchrony, it creates RV-LV dyssynchrony and LV-LV dyssynchrony because pacing begins in the right ventricle and crosses the septum before activating the LV lateral wall. Preserved synchrony optimizes stroke volume, which is desirable during the perioperative environment. Therefore, in the perioperative environment, it is advantageous to maintain intrinsic cardiac conduction as much as possible if the surgical procedure and use of EMI permits. In contrast, CRT devices attempt to ensure pacing 100% of the time in order to optimize stroke volume.

The manufacturer and model should be noted, along with the indication for placement of the CIED, in order to troubleshoot problems. Theoretically all patients with CIEDs should carry identification cards that identify the type of CIED, the manufacturer, the model, and date of implantation. In practice, many patients do not carry their CIED cards, and it is left to the anesthesia provider to identify these parameters. There are several methods for obtaining this information. Frequently an interrogation note from the CIED team will identify all these parameters. Occasionally, patients present for elective surgery without CIED team communication. In this subset of patients, there are several options. One option for identifying the type of device and manufacturer is the use of chest radiographs (Fig. 38.1). Chest radiographs can identify pacemakers versus ICDs, due to the increased thickness of the shocking coil in ICDs. Chest radiographs can also identify CRT devices due to the lead in the coronary sinus. With some training, the manufacturer can also be identified via chest radiograph (Fig. 38.2). In situations where the patient does not have his or her card, or there is no CIED note and there is no chest radiograph available or it cannot be interpreted, then contact with the CIED manufacturers can be initiated, since they all keep clinical records of their patients. Communicating directly with the manufacturer can disclose information about the type of CIED, date of implantation, and original settings. Unfortunately, current information about pacemaker dependence and battery life is not usually available by phone.

Battery longevity is important to consider as an anesthesia provider. Three months of battery duration is reasonable in the perioperative period. This time point is chosen because battery life depends on the amount of pacing and the number of shocks delivered for pacemakers and ICDs, respectively. The burden of pacing in the perioperative period may be very different than the patient's normal requirements. Sinoatrial (SA) and AV nodal suppressing agents such as opioids, beta-blockers, and calcium channel blockers administered in the hospital may increase pacing requirements; therefore it is prudent to have several months of battery life remaining. In addition, there may be unexpected postoperative complications leading to the increased duration of hospitalization. If a patient is presenting for elective surgery with a diminished battery life, the generator should be replaced prior to the surgery.

It is important to establish if the patient is pacemaker-dependent, which is defined as the absence of a perfusing rhythm without pacing. In order to establish pacemaker dependence, a history and chart review may identify an episode of bradyarrhythmia leading to syncope. In addition, for patients with refractory SVT, they will occasionally have an AV nodal ablation. This is a therapeutic procedure that establishes complete heart block to eliminate rapid ventricular response to SVT. This patient population is pacemaker-dependent. Patients with CRT devices can be considered pacemaker-dependent even if they have a normal sinus rate and intact AV conduction due to

TABLE 38.3 Summary of Information Anesthesiology Team Should Identify Prior to Surgery

Perioperative Considerations	Comments
Last CIED interrogation	12 months for pacemakers 6 months for ICD/CRT
Type of device	Pacemaker ICD CRT Loop recorder
Manufacturer	Obtained via patient card, history, CIED note, chest radiograph, or telephone call to manufacturer
Battery life	Suggested >3 months
Pacemaker dependence	Underlying rhythm CRT devices should be paced 100%
Magnet response	Differs by manufacturer and battery life
Pacing threshold	Should be set several times higher for safety

CIED, Cardiac implantable electronic devices; *CRT*, cardiac resynchronization therapy; *ICD*, implantable cardioverter-defibrillator.

the hemodynamic deterioration they suffer with dyssynchrony of the RV-LV and LV-LV. Pacemaker dependence can be established by the CIED team preoperatively. They can decrease the pacing rate in a stepwise fashion to search for intrinsic electrical activity. If no intrinsic rate is present around 40 to 45 beats/min or the patient develops symptoms, the patient may be considered pacemaker-dependent. Some patients who are not pacemaker-dependent may become pacemaker-dependent in the perioperative period due to SA and AV nodal blocking agents; therefore, it is important to be prepared to address this clinical scenario. If the patient is deemed to be pacemaker-dependent, a secondary method for pacing the patient should be considered in the event of a pacemaker failure. Alternative methods of pacing patients intraoperatively include transesophageal pacing, transcutaneous pacing, or transvenous pacing through a pacing pulmonary artery catheter or through a temporary transvenous pacing wire. Transesophageal pacing activates the left atrium, which is in close proximity to the esophagus, so this type of pacing depends on intact AV node conduction. It will not work for heart block. Transcutaneous pacing depends on correct pad position and high pacing outputs, which can be very uncomfortable in a nonsedated patient. Transvenous pacing and pacing pulmonary artery catheters can be time consuming, and they are not ideal choices for emergent pacing. Whatever method is chosen, it is important to have the necessary equipment and support organized and available prior to beginning the procedure. A summary of important information for the anesthesia team to identify is summarized in Table 38.3.

ELECTROMAGNETIC INTERFERENCE

EMI in the preoperative setting can interfere with the functioning of both pacemakers and ICDs.[22,23] EMI may inhibit pacing, damage the lead-tissue interface, damage the pulse generator, and/or trigger an electric reset mode, particularly if the source of EMI is within 6 inches (15 cm) of the CIED generator.[24] Although there are several potential sources of EMI, the most commonly encountered source is monopolar electrocautery. Monopolar electrocautery is the most frequently used type of electrocautery because it has both cutting as well as coagulation capabilities. Monopolar electrocautery creates a current that passes from the probe to the tissue and returns through the patient to the return pad to create an electrical circuit. Bipolar electrocautery is usually not a concern[25]; the electrical current field is small and limited to the two poles at the end of the electrode. Unfortunately, bipolar is less frequently used compared with monopolar electrocautery and is usually reserved for neurosurgery, ophthalmology, and head and neck procedures. Bipolar electrocautery does not cause EMI of CIEDs unless it is applied directly to a CIED, and there are minimal clinical circumstances where that would be indicated. The vast majority of electrocautery encountered in the operating suite is monopolar due to its versatility.

Modern CIEDs have evolved to produce better shielding from EMI, and adverse events from EMI are much less common with improvements in CIED technology.[24-27] Shielding reduces the potential to induce oversensing in the CIED. Oversensing in a pacemaker means the pacemaker "sees" the EMI-generated artifacts as intrinsic cardiac electrical activity and therefore does not initiate a paced rhythm. Such failure to initiate a paced rhythm (inhibition of the pacemaker) can compromise hemodynamics in a pacemaker-dependent patient. If oversensing occurs in an ICD, EMI may be misinterpreted by the ICD as a malignant tachyarrhythmia, which may cause the patient to receive an inappropriate shock. It is important to note that it is not only the location of monopolar electrocautery that is critical to proper CIED function, but it is also the location of the grounding pad that is critical to avoid CIED malfunction. The HRS/ASA Expert Consensus Statement suggests that due to the decreased likelihood of EMI-related interference seen when surgery is below the umbilicus, the patient should proceed to surgery with no magnet application to the device or reprogramming. This assumes that the monopolar electrocautery grounding pad or return pad is also placed below the level of the umbilicus. If current is traveling above the level of the umbilicus, there is significant risk of EMI of the CIED. For procedures above the umbilicus with no EMI from the surgical procedure, the patient may also proceed for surgery without routine magnet use or device reprogramming. For all patients presenting for surgery with CIEDs, there should be a magnet available with the magnet function of the device known in case of a change in the surgical plan or unexpected EMI. Magnet function is discussed in the next section.

MAGNETS

Magnet applications for CIEDs were originally intended to investigate battery life of the device, and they were not created for perioperative management of CIEDs, although that is probably their most common utilization at this time. When magnets are applied to the pacemaker, the effect on the device depends on the manufacturer, in addition to the battery life. For example, when a magnet is applied to a Medtronic pacemaker, the device will pace asynchronously. If the Medtronic device is a single-chamber pacemaker, it will pace that single chamber asynchronously. If the Medtronic device is a dual-chamber pacemaker, it will pace both chambers asynchronously. However, the rate at which the pacemaker will pace depends on battery life. If the Medtronic pacemaker has adequate battery life, the device will pace at 85 beats/min. However, if the battery life is at the elective replacement interval, the device will pace at 65 beats/min. The change in rate is binary, meaning that the rate goes from 85 to 65 beats/min when the battery enters its elective replacement interval. Different manufacturers have difference responses to magnet application. St. Jude pacemakers will pace asynchronously during magnet application if the magnet response is turned on. It is important to note that magnet application is programmable—that is, with some devices, magnet application will have no effect. The effect of magnet response is an important piece of information to obtain from the CIED team. For a St. Jude pacemaker with magnet response programmed on, magnet application will program the device to pace asynchronously at a rate of 100 beats/min if the battery life is normal or a rate of 85 beats/min if the device is at its battery elective replacement interval. Unlike Medtronic devices, the rate change from 100 to 85 beats/min is not binary; it is a gradual reduction from 100 to 85 beats/min.[3]

Magnets continue to be very popular in everyday practice for the management of CIEDs. This is a relatively easy way to render the pacemaker asynchronous, with the added benefit of the device reverting back to its programmed settings once the magnet is removed. Importantly, the asynchronous rate provided by magnet placement may not be appropriate for the patient for a particular procedure. At times, patients require a higher heart rate in order to increase tissue oxygen delivery. To the contrary, most magnet rates are typically around 90 beats/min, which may not be appropriate for a large subset of patients—that is, those with aortic stenosis or coronary artery disease. These variables make it important to confirm the magnet effect on each individual patient's device before the procedure, and to have an individualized plan for each patient.

The choice of reprogramming versus magnet application largely depends on the type of surgery, patient position, accessibility of a programmer, and knowledge of magnet function of a particular patient's device. It should be emphasized that a magnet has different effects when applied to a pacemaker or to an ICD. In a majority of pacemakers, magnet application induces an asynchronous mode. Magnet application to an ICD inhibits tachyarrhythmia detection, thus preventing therapy (i.e., delivery of shocks). However, it does *not* change the mode of the underlying pacemaker. Therefore, a magnet placed over an ICD will not induce asynchronous mode in the underlying pacemaker. For patients with an ICD who are pacemaker dependent, reprogramming is the preferred option if EMI is a significant concern. One advantage of reprogramming are that if the patient is not in the supine position, it may be difficult to maintain the magnet in a location over the device to render it asynchronous. This is particularly true in the prone position. If the patient has a normal sinus rate, adequate chronotropy, and intact AV node conduction, magnet application may compete with the patient's own heart rate if surgical stimulation increases the sinus rate. This can lead to significant arrhythmias caused by depolarization of the ventricle by the pacemaker during a refractory period, due to intrinsic electrical activity. The principal disadvantage of reprogramming versus magnet application is that the changes made with the programmer are not as easily reversed. If the patient develops an arrhythmia or has an increased sinus rate, it may be difficult to reprogram the device intraoperatively, depending on programmer availability and CIED team presence. The other disadvantage of reprogramming a CIED compared with magnet application involves the human factor. Failure to re-enable tachyarrhythmia therapy following surgery can lead to catastrophic consequences for patients with CIEDs. It is important to understand the risks and benefits of magnet application versus reprogramming, and create a perioperative plan that suits the patient.

ELECTROMAGNETIC INTERFERENCE DAMAGE TO THE CARDIAC IMPLANTABLE ELECTRONIC DEVICE

EMI is an important consideration for anesthesiology providers because of oversensing. It is uncommon for modern CIEDs to be damaged by EMI from the operative environment; however, some particular complications will be discussed. Monopolar electrocautery that is done in very close proximity to the pulse generator may directly damage the myocardium at the interface with the CIED lead. This can trigger arrhythmias or loss of pacing capture due to increases in pacing thresholds.[28] Therefore, it is recommended that bipolar electrocautery should be used when electrocautery is performed in close proximity to the pulse generator. Another complication that may happen due to ionizing radiation is device reset.[29,30] It is uncommon for even monopolar electrocautery to cause reset. In the perioperative setting, this very rarely occurs when an energy surge directly contacts the pulse generator, resulting in a major hardware/software failure. The reset mode is unique to each manufacturer and serves as a safety backup in the case of catastrophic failure. Unfortunately, magnet application and device reprogramming will not prevent electrical reset. The best way to prevent reset is to ensure that EMI is as far as possible from the pulse generator (ideally >15 cm). If a patient's CIED does go into reset mode, the pacemaker will commonly revert to a ventricular demand pacing (VVI) mode between 65 and 70 beats/min. Magnet response in reset mode will also vary among manufacturers. ICDs will have a wide range of rate cutoffs for VT detection in the reset mode. ICD pacing will be typically in a VVI mode again around 65 to 70 beats/min. Electrical reset should prompt consultation with a CIED team to ensure proper device functionality.

INTRAOPERATIVE MANAGEMENT

The intraoperative management of CIEDs naturally evolves from a thoughtful preoperative plan. A pathway for management of CIEDs during nonemergent surgery is outlined in Fig. 38.3. Pacemaker patients who are pacemaker-dependent and who are having surgery with monopolar electrocautery within 15 cm of the generator should have their

device reprogrammed to avoid pacemaker oversensing of electrocautery as intrinsic cardiac function. This could lead to underpacing and hemodynamic collapse in pacemaker-dependent patients. For patients in the supine position with known magnet function who have magnet rates appropriate for their concurrent comorbidities, placement of a magnet over a pacemaker is a reasonable approach for patients at risk for monopolar electrocautery oversensing. Whether the prescription plan is reprogramming or magnet application, the rate responsive features of the device should be disabled. The rate response is the fourth letter in the 2002 NAPSE guidelines and refers to increasing the heart rate above the lower rate limit when the patient has increased metabolic demand (e.g., exercise). Rate response sensors commonly use minute ventilation or thoracic impedance to increase rate, and both may be affected intraoperatively. Patients on mechanical ventilation will see increases in heart rate if the minute ventilation is increased with these sensors. For patients with thoracic impedance sensors, electrocautery may lead to increases in heart rate. Although these increases in heart rate may be transient, they may be detrimental for patients in whom strict heart rate control is optimal. In addition, these changes in heart rate may be distracting for the anesthesia provider, who may perceive the heart rate fluctuations as CIED malfunction. Patients with ICDs should have their tachyarrhythmia therapies disabled to avoid inappropriate shocks from monopolar cautery oversensing by either reprogramming or magnet application if EMI (or the return pad) is used above the umbilicus. Patients with ICDs who are pacemaker dependent with close EMI to the generator are a special group that must have their devices reprogrammed. Magnet application is not a reasonable strategy in these patients, since the magnet will not make the pacemaker asynchronous. Patients who have CRT devices are another special classification of patients presenting for surgery. Again, most dual-chamber pacemakers are programmed to minimize RV pacing. CRT devices are programmed to achieve ventricular pacing 100% of the time to improve cardiac output, systolic, and diastolic function. Even though CRT devices are pacing the ventricle 100% of the time, they will not have the characteristic wide complex QRS found in RV pacing alone. Programming the CRT device to an asynchronous mode above the intrinsic rate is a reasonable intraoperative management strategy. Since almost all CRT devices are ICDs, magnet application to the device will deactivate tachyarrhythmia therapy but will not make the CRT device asynchronous. It is critical to reprogram CRT devices to an asynchronous mode if EMI is used above the umbilicus. Brief periods of monopolar electrocautery may be tolerated in patients with CRT devices who have a reasonable sinus rate and normal conduction if the device is not reprogrammed. However, prolonged use of monopolar electrocautery will lead to hemodynamic deterioration due to a loss of synchrony between the RV and LV and the LV septal and lateral walls.

Intraoperative monitoring mirrors standard American Society of Anesthesiology (ASA) guidelines. Plethysmographic pulse oximetry is invaluable for patients with CIEDs undergoing surgery because it is the best clinical indicator that the pacemaker is capturing and creating cardiac output. With monopolar electrocautery, monitoring for pacemaker capture with ECG can be challenging. Due to ECG technology, the ECG rate will sometimes double count the heart rate due to counting of a pacemaker spike and the resulting QRS complex. Double counting of the heart rate may lead to erroneous patient management. In addition, pacemaker spikes may be difficult to see due to their low voltage. Pacemaker spikes may be accentuated with various patient monitors; however, they may inaccurately identify a pacemaker spike. It is important to ensure that each pacemaker spike is capturing the myocardium. Ensuring the paced rate of the device is the same as the pulse oximetry rate ensures proper capture of the myocardium and appropriate cardiac output. While arterial lines accurately display pacemaker capture and cardiac output, patients with CIEDs do not need routine arterial line placement unless patient acuity or surgical complexity deems it necessary.

If a patient requires central venous access or a pulmonary artery catheter, it is important to be mindful of CIED leads placed within 1 to 2 months prior to the planned surgical procedure. The risk for dislodging new leads in the right atrium and right ventricle is higher until the leads become fixed within the myocardium. Patients with CRT devices have a coronary sinus lead that can be more easily dislodged when compared with a chamber lead, since there is no mechanism of lead fixation in the coronary sinus.

POSTOPERATIVE MANAGEMENT

Patients with CIEDs should be appropriately monitored in a clinical environment that is tailored to their postoperative risk. There does not need to be escalation of postoperative disposition based on the presence of a CIED alone. The patient acuity and operative course should be the major drivers for postoperative disposition. For example, patients presenting for outpatient surgery require routine postoperative continuous monitoring until they meet discharge criteria. Most patients with CIEDs do not require routine interrogation following surgery; however, there are notable exceptions. It is reasonable to evaluate patients with CIEDs within 1 month of their surgery on an outpatient basis.[3] For some patients, they must have their device interrogated prior to leaving a monitored setting, whether that is the postanesthesia care unit or a monitored bed. Patients who have had their tachyarrhythmia therapy disabled for surgery must have their device reprogrammed and their tachyarrhythmia therapy re-enabled prior to leaving a monitored setting. In addition, patients who have undergone hemodynamically significant procedures with large volume shifts should have their device interrogated to ensure proper sensing and capture. Patients receiving cardioversion, defibrillation, and therapeutic radiation are at risk for device reset, and should have interrogations as well in the immediate postoperative period.[3] Patients who fall into high-risk categories are more likely to have a change in CIED functionality. Part of the preoperative communication between the CIED team and the anesthesia team should address the need for CIED interrogation postoperatively. Identifying patients who need CIED interrogation prior to discharge avoids lapses in communication in the postoperative period.

EMERGENCY PROTOCOL

Patients with CIEDs may present for urgent or emergent surgery. In these instances, the bidirectional communication between the CIED and anesthesiology teams may not be feasible. When these clinical scenarios present themselves, it is important for the anesthesiology team to identify several components of the CIED in a time efficient manner (Table 38.4). As described previously, the anesthesiology team can get this information from the patient's CIED wallet card, medical records, or CIED team note, or from the chest radiograph. If these methods do not provide pertinent information, the anesthesiology team should call the device manufacturer to obtain basic information regarding the type of device and date of implantation (Table 38.5).

During an emergency procedure, it is important to establish whether the patient is pacemaker dependent. In the absence of a CIED note, a 12-lead ECG or rhythm strip can be examined to look for pacemaker spikes. If the majority of QRS complexes are preceded by a pacing spike, the patient should be treated as pacemaker dependent. The risk of EMI to the CIED should be established using the criteria previously presented, including the use of monopolar versus bipolar electrocautery, in addition to the location of EMI and the return pad. For pacemaker patients who are pacemaker dependent, it is reasonable to use a magnet for surgeries requiring EMI above the umbilicus. However, it is important to remember that a minority of pacemakers will have the magnet function turned off. Therefore, the anesthesiologist should monitor the pulse oximeter to ensure that there is no oversensing of the EMI leading to a lack of pacing in pacemaker-dependent patients, even when the magnet is applied to the device. For patients who are not pacemaker dependent, it is reasonable to have a magnet available in case the patient requires asynchronous pacing. For patients with ICDs, defibrillator pads should be placed on the patient during emergency procedures. Magnet application should be applied for cases with EMI above the level of the umbilicus. Since this will not render the pacemaker asynchronous, if monopolar EMI is used above the umbilicus, it is critical for the surgeon to use short bursts (<5 seconds) of monopolar electrocautery to avoid pacemaker

oversensing. Interrogation of the CIED under the direction of a physician knowledgeable in the function of these devices should be done as soon as possible. The emergency protocol is described in the HRS/ASA Expert Consensus Statement. A suggested emergency algorithm is shown in Fig. 38.4.

It may be challenging for anesthesiology providers to feel comfortable reprogramming CIEDs in the perioperative environment. Having a structured CIED team that is willing to work with anesthesiologists is a great way to learn how to reprogram devices. Even if one does not feel comfortable reprogramming CIEDs in the perioperative environment, it may be very important for the anesthesiologist to know how to turn on a programmer to obtain important information about a device during an emergency procedure. Interrogating a device and simply reading the home screen can provide critical information regarding the type of device (pacemaker, ICD, CRT), the pacemaker mode, histograms of percentage of time the patient is being paced, battery life, and lead impedance. This is relatively easy to do if one has access to a device programmer in one's institution. Sample images of home screens are shown in Fig. 38.5.

SPECIFIC SURGICAL PROCEDURES

The general perioperative recommendations as outlined before cover the majority of clinical scenarios encountered by anesthesia providers caring for patients with CIEDs. However, there are specific surgical procedures that convey increased risk for CIED malfunction or damage due to high therapeutic energy transfer to the CIED.

Cardioversion

External cardioversion may occur as a planned procedure or as part of advanced cardiovascular life support (ACLS) to treat unstable arrhythmias. Historically, there was increased concern for CIED function because of the use of unipolar leads. With these older leads, the current traveled from the generator (one pole) to the tip of the lead (second pole). There were reports of loss of capture and electrical reset when the cardioversion pads were placed in an anterior and lateral orientation.[31,32] With newer leads, which have a bipolar configuration (both poles located in the tip of the lead), it is uncommon for cardioversion to affect CIED function. In a study with 44 patients, no CIED malfunction was observed during cardioversion with an anterior–posterior pad orientation with the anterior pad more than 8 cm from the CIED generator.[33]

Radiofrequency Ablation

Many patients with CIEDs present to the electrophysiology laboratory for electrophysiology studies and catheter ablation. It is uncommon to have CIED malfunction with radiofrequency ablation (RFA); however, if complications occur, they involve electrical reset, oversensing, and undersensing due to energy delivery near CIEDs. Recommendations include avoiding direct contact between the ablation catheter and the pulse generator and leads, and keeping the path of radiofrequency current (electrode tip to current return pad) as far away from the pulse generator and leads as possible.[34,35]

Lithotripsy

Extracorporeal shockwave lithotripsy is used for disintegrating renal calculi. From the initial use of lithotripsy, there was theoretical concern that the shockwaves and EMI would damage CIEDs; therefore, CIED presence was originally a contraindication to lithotripsy. As technology has evolved, current lithotripsy requires less energy transfer to the patient with improved focus of energy, as well to the renal calculi. Guidelines from Canada recommend a

distance of 15 cm from the device to treatment area and that abdominal CIEDs are contraindicated.[36] Another study suggests that with improved technology for lithotripsy, most CIEDs do not have complications; however, if complications arise, the device should be reprogrammed immediately by a member of the CIED team.[37]

Radiation

Diagnostic radiation usually does not significantly affect CIEDs. On the other hand, therapeutic radiation can significantly affect CIED function if directed onto the pulse generator.[38-40] If radiation therapy is performed, position the device outside the field of radiation. The concern with therapeutic radiation and CIEDs is that the circuit of the CIED may be damaged directly by the radiation. Direct radiation of CIEDs should be avoided, and accumulated doses should be kept under 5 Gy.[3] In some instances, the pulse generator will require surgical relocation prior to commencing radiation.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) involves direct electric current to the brain for the treatment of depression. There are no reports of direct damage to the CIED; however, the concern is pacemaker oversensing of the electric current leading to underpacing in pacemaker-dependent patients. The medical decision to use ECT should consider the duration of its application. If the therapy is going to be short (<5 seconds), it is unlikely that hemodynamically significant oversensing will occur. It is also unlikely that the patient will receive an inappropriate shock. If prolonged ECT exposure is required, the device should be placed in asynchronous pacing mode and antitachyarrhythmia function should be disabled. A discussion between the CIED team and the psychiatrist may facilitate treatment plans, since these patients usually undergo multiple treatments of ECT. ECT may lead to significant hemodynamic effects unrelated to the CIED, including sinus tachycardia from the seizure and ventricular arrhythmias. A magnet should be available for all patients undergoing ECT in the event that oversensing of myopotentials or inappropriate therapy for sinus tachycardia occurs.[3]

Endoscopy

Most upper and lower endoscopies do not use electrocautery, and for those cases, CIED management is straightforward. However, occasionally, electrocautery is used for some patients. There are case reports of inappropriate ICD therapy in these patients. When electrocautery is planned for endoscopy, the same guidelines as previously presented apply with regard to CIED team communication and the assessment of EMI risk to the CIED.

Emerging Technologies

The past couple of years have seen the advent of a new, leadless pacemaker. The impetus for the development of a leadless pacemaker stems from the fact that many pacemaker complications are related to the leads themselves, including lead fracture and infection. Currently, the Medtronic Micra is the only leadless pacemaker approved for use in the United States. The Micra is a single-chamber device placed in the right ventricle via the femoral vein. Its modes include VVIR, VVI, VOO, and OVO. Because these devices are so new, there is very little data on how to manage these patients in the perioperative period. Because of their small size, these devices do not have a magnet sensor and thus will not respond to a magnet. It is recommended that these devices be reprogrammed to VOO mode to reduce oversensing when EMI is anticipated.[41] It should be noted that these devices use the same programmer as their full-size counterparts.

A new type of ICD is now on the market, and its use continues to grow: the subcutaneous ICD (S-ICD) manufactured by Boston Scientific Inc. A driving force for the design of this pacemaker is similar to the Micra pacemaker. Transvenous systems such as the most common CIEDs on the market may be challenging in patients with difficult vascular anatomy. In addition, the removal of transvenous systems can be complicated in the setting of long-standing CIED placement, requiring a laser lead extraction. This system was initially approved in 2012 as defibrillation therapy and is being used in patients at risk for malignant ventricular arrhythmias who do not have a need for bradycardia pacing, or antitachycardia pacing to manage VT.[42] Although this device is not able to provide long-term pacing, it is capable of pacing at 50 pulses/min for 30 seconds after a defibrillatory shock, should the patient become profoundly bradycardiac posttreatment.[43]

The S-ICD consists of a pulse generator and a single subcutaneous lead. Both the pulse generator and the lead are implanted in the subcutaneous tissue and are extrathoracic.[44] Currently, the S-ICD can only be implanted in the left chest. The pulse generator is usually implanted between the anterior and midaxillary lines at the level of the sixth intercostal space. The lead is then tunneled medially from the pulse generator pocket to the xiphoid process and then superiorly along the left parasternal border.

Although different in its makeup, the S-ICD has the same response to a magnet as a traditional ICD. That is, magnet application over the pulse generator will turn off the antiarrhythmic features of the device, and removing the magnet will revert the device to its prior programmed state. A feature the S-ICD has that ensures the magnet is properly positioned is a beeping sound that indicates that arrhythmia detection and shock therapy have been suspended. If the beep is not heard with magnet application, the magnet should be repositioned over the device until a beep is elicited. Due to the location of the ICD at the midaxillary line, it is best to reprogram this device in the perioperative setting to turn off the antitachycardic function. When the device is reprogrammed, defibrillator pads should be placed on the patient.

Conclusions

Anesthesiologists should have a basic understanding of CIEDs and also the nuances of managing this subset of patients in the perioperative period. As technology continues to evolve, and as the population lives longer and indications for CIED therapy continue to grow, perioperative physicians will encounter this patient population more frequently. It should also be noted that at times, trained CIED experts (cardiologists, manufacturer representatives) are not available, making it the anesthesiologist's duty as a true perioperative physician to be able to fully care for these patients.

Acknowledgment

The editors and publisher would like to recognize Dr. Marc A. Rozner for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Neurologic Monitoring

CHRISTOPH N. SEUBERT, JOHN J. MCAULIFFE III, and
MICHAEL MAHLA

KEY POINTS

- There are four key principles of intraoperative neurologic monitoring.
  - The pathway at risk during the surgical procedure must be amenable to monitoring.
  - The monitor must provide reliable and reproducible data.
  - If evidence of injury to the pathway is detected, there must be some intervention possible.
  - If changes in the neurologic monitor are detected, and no intervention is possible, although the monitor may be of prognostic value, it does not have the potential to provide direct benefit to the patient from early detection of impending neurologic injury.
- There are few randomized prospective studies evaluating the efficacy of neurologic monitoring modalities.
- Anesthesiologists can improve the efficacy of monitoring by maintaining good physiologic homeostasis and stable levels of anesthesia during parts of the surgical procedure that place the nervous system at greatest risk.
- Based on clinical experience and nonrandomized studies, four practice patterns for use of neurologic monitoring have emerged:
  - There are procedures for which monitoring is recommended and used by most centers.
  - There are procedures for which monitoring is used frequently in some centers, but not in others.
  - There are procedures for which there is no clear clinical experience or evidence indicating that monitoring is useful at all (experimental use).
  - There are procedures in which monitoring is used selectively for patients believed to be at higher-than-usual risk for intraoperative neurologic injury.
- Good communication between surgeon, anesthesiologist, and neurophysiologist is essential to optimizing the utility of monitoring.

Neurologic monitoring during anesthesia care for a patient spans a wide spectrum of techniques, diverse procedures, and various intraoperative or even postoperative settings. Techniques for monitoring fall into two broad categories: techniques to assess metabolic integrity of the nervous system, which typically entail either global or regional determinations of blood flow or oxygenation; or techniques to assess functional integrity, which likewise may be global or focused on specific anatomic pathways or structures of the nervous system. Neurologic monitoring implies that the data for the assessment of the integrity of the nervous system are acquired on a continuous or frequent intermittent basis rather than just at the beginning and end of a procedure.

The procedures and settings in which neurologic monitoring is typically applied all share the characteristic that changes in the monitored parameters can be corrected or minimized by either modifying the surgical approach or manipulating parameters under the control of the anesthesiologist. Monitored procedures range from procedures where monitoring dictates the surgical approach, such as localization of the motor strip during tumor surgery or the neurologic examination during an "awake" craniotomy, to procedures that by their nature put parts of the nervous system at increased risk.

In many procedures that require neurologic monitoring, the anatomical target is also susceptible to drugs administered in the course of an anesthetic. The anesthesiologist and the surgeon need to be aware not only of limitations inherent in individual monitoring techniques, but also of nonsurgical factors that influence the monitoring results. The monitoring approach ideally should anticipate nonsurgical factors by providing a degree of redundancy that helps distinguish a localized surgical trespass from a systemic event.

The application of neurologic monitoring to a surgical procedure may be organized in different ways. It may simply consist in setting up a piece of monitoring equipment, such as a facial nerve monitor that provides acoustic feedback to the surgeon. At the other end of the spectrum, it may require the dedicated services of a technologist and a neurophysiologist in addition to the surgical and anesthesia teams as would be the case during the mapping phase of the resection of a brain tumor. Between those extremes are a variety of delivery models for intraoperative neurophysiologic monitoring that may entail components of telemedicine. Regardless of the organizational structure, the utility of intraoperative neuromonitoring will depend on a shared understanding of surgical objectives, anesthetic constraints, and limitations of monitoring. This shared understanding will then need to be supported by open lines of communications by all involved, particularly during critical phases of an operation.[1]

For some procedures, neurologic monitoring is a marker of the quality of care and is routinely employed because outcome data support its use. Examples include correction of scoliosis and resection of vestibular schwannomas. More frequently, the approach to monitoring is based on local conventions and surgical expectations. In this latter case, monitoring utility depends even more on a good understanding of the technique's capabilities and limitations by anesthesiologists, surgeons, and the intraoperative monitoring team; on good communication; and on their mutual collaboration to allow corrective action in the face of changing signals or to prevent false alarms that disrupt surgery.

This chapter first discusses individual monitoring modalities in isolation so that the clinician can appreciate the inherent strengths and weaknesses of each. Subsequent sections apply this information by describing suitable approaches to various clinical settings that combine and integrate individual techniques to optimize neurologic outcome for patients. The chapter ends with a brief discussion of how neurologic monitoring is believed to be useful today, and where more work is needed to determine whether monitoring has a role in surgical patients in the future.

Monitoring Modalities

MONITORS OF ADEQUACY OF NERVOUS SYSTEM BLOOD FLOW

Adequacy of cerebral blood flow (CBF) can be monitored by two principal methods. The first method assesses blood flow itself with the implicit assumption that "normal" flow provides adequately for the metabolic needs of the brain. The second approach assesses oxygen delivery either locally or globally with the implicit assumption that normal oxygen delivery at the site of measurement reflects adequate blood supply throughout the central nervous system (CNS). To illustrate the limitations imposed by such implicit assumptions, let us examine global or hemispheric CBF in the context of a patient's disease process.

In normal brain, values of hemispheric CBF of approximately 50 mL/100 g/min reflect adequate oxygen delivery for maintaining structural integrity and function. Values of less than 20 to 25 mL/100 g/min are associated first with failure of function and on further decrease with structural damage.[2] In neurosurgical patients, structural integrity and function may be altered by disease processes and anesthetics, which have an impact on the interpretation of measured CBF. A CBF of 40 mL/100 g/min in a patient in barbiturate coma after resection of an arteriovenous malformation may represent hyperemia (because metabolic demand is very low), whereas the same CBF in a patient with a mass lesion may reflect a modest decrease in cerebral perfusion pressure secondary to increasing intracranial pressure. Thus the clinical response to an abnormal value requires context and clinical judgement.

Global Blood Flow Monitoring Techniques (Noninvasive)

Intravascular Tracer Compounds. Direct measurement of CBF is possible by determining kinetics of wash-in and/or wash-out of an inert tracer compound, a method originally described by Kety and Schmidt.[3] A widely used modern variation of the same concept is the imaging of the first passage of intravascular contrast agents during computer tomographic or magnetic resonance imaging for determining loco-regional blood flow (Fig. 39.1). These techniques share the limitation of providing a snapshot of CBF in time instead of continuous assessment of flow over time.

Transcranial Doppler Ultrasound. Transcranial Doppler (TCD) ultrasound is a technique that infers CBF from measurements of the blood flow velocity in the large conducting arteries of the brain. The TCD probe transmits pulses of sound waves through the thin temporal bone in a variation of the pulsed wave Doppler technique with which anesthesiologists may be familiar from echocardiography. When these sound waves are reflected off the red blood cells back toward the TCD probe, the velocity of the reflected sound waves is changed because the blood cells themselves are in motion toward or away from the probe. This phenomenon is known as the "Doppler shift," and is directly related to flow velocity and flow direction of the blood cells. Blood flow is faster during systole and in the center of a vessel whereas it is slower in diastole and near the vessel wall. TCD records a spectrum of flow velocities whose outline resembles an arterial waveform tracing. These concepts are illustrated in Fig. 39.2.

Intraoperatively, TCD measurements are most commonly and easily made by continuous monitoring of the middle cerebral artery for the purpose of detecting either significant changes in flow velocity or the presence of particulate emboli.[4] As a diagnostic study, segments of all proximal intracranial arteries and the internal carotid artery of the neck can be insonated. An important limitation of TCD results from the fact that most of the examination is done through the temporal bone, which may be thick enough to preclude an adequate examination in 10% to 20% of patients.[5,6]

Two assumptions that are intuitive and plausible, but ultimately unproven, must be made for TCD-measured blood flow velocity to have a direct relationship to CBF. First, blood flow velocity is directly related to blood flow only if the diameter of the artery where the flow velocity is measured and the measurement angle of the Doppler probe remain constant. In practical terms, the difficulty with this assumption lies in finding a means to affix the TCD probe in a way that prevents dislodgment or movement during monitoring. The second assumption requires that CBF in the basal arteries of the brain is directly related to cortical CBF. Because TCD monitoring is typically done using the middle cerebral artery, this assumption may be invalid if collateral blood flow by leptomeningeal collaterals from anterior and posterior cerebral artery territories is adequate. Although these two assumptions constrain the utility of TCD as a stand-alone monitor of CBF, the changes in flow velocity seen in typical applications (discussed subsequently) are large enough to provide useful clinical information.

More importantly, TCD is the only continuous neurologic monitoring technique that provides early warning for hyperperfusion and for the number of emboli delivered to the brain during various phases of an operation. Because of their high echogenicity, emboli show up in the TCD spectrum as high-intensity transient signals (see Fig. 39.2) and are easily identified as brief beeps or chirps within the background of the Doppler sounds.

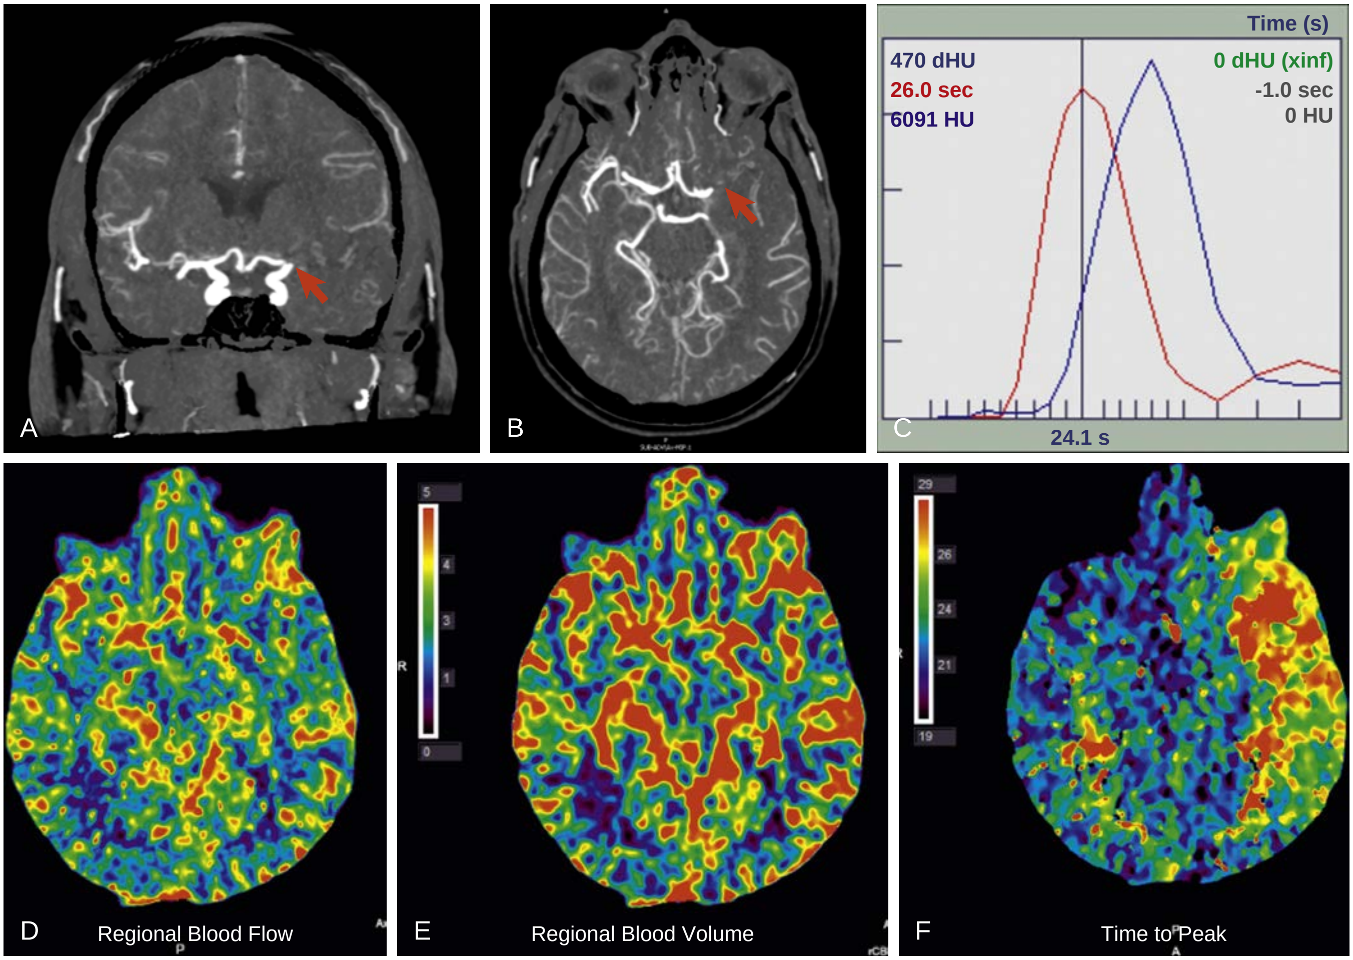

Fig. 39.1 Determination of cerebral blood flow by means of an intravascular tracer. Shown are computer tomographic images of a patient 90 minutes after onset of a left middle cerebral artery stroke. The site of the occlusion in coronal (A) and axial (B) planes is indicated by a red arrow. Panel C shows the arterial inflow function and venous outflow function derived by repeated imaging of the passage of radiopaque contrast through a volume element (voxel) representative of arterial and venous territory, respectively. The A2 segment of the anterior cerebral artery is typically chosen as a voxel for the arterial inflow function and the superior sagittal sinus for the venous outflow function. Based on these functions, blood flow, volume, and flow kinetics can be calculated for other areas of the image. The cerebral blood flow map (D) shows symmetrical flow in both hemispheres, with warmer colors indicating areas of higher flow consistent with grey matter. Blood volume (E) is symmetrical as well, but the time to the peak concentration of contrast (F) is significantly delayed for brain affected by the stroke.

Jugular Bulb Venous Oxygen Saturation. The degree of oxygen extraction by an organ can be monitored by following the oxygen saturation of the mixed venous blood that drains that organ. In the case of the brain, jugular bulb venous oxygen saturation (Sjvo$_2$) is believed to measure the degree of oxygen extraction by the brain and to represent the balance between cerebral oxygen supply and demand. To monitor Sjvo$_2$, a fiberoptic catheter is placed in a retrograde fashion into the jugular bulb through the internal jugular vein under fluoroscopic guidance. Correct tip placement is crucial to minimize admixture of extracranial venous blood. To decrease the risk of complications, usually only one side is monitored.

Several theoretical limitations of the technique must be borne in mind to interpret Sjvo$_2$ values and trends properly. Although nearly all blood from the brain drains via the jugular veins, intracranial mixing of venous blood is incomplete and may result in differences between right-sided and left-sided measurements. The dominant jugular vein (i.e., the right for most patients) drains predominantly cortical venous blood, whereas the contralateral jugular vein drains more of the subcortical regions.[7] Despite such regional differences, Sjvo$_2$ must be considered a monitor of global cerebral oxygenation because inadequate perfusion to a focal brain region may not decrease Sjvo$_2$ values below the normal range of 55% to 75%. Because Sjvo$_2$ represents the balance between supply and demand, interpretation of the absolute value of Sjvo$_2$ must take the clinical circumstances into account.

Cerebral Oximetry. Cerebral oximetry is a noninvasive technique that, similar to Sjvo$_2$, uses reflectance oximetry to measure the oxygen saturation of the tissues underneath the sensor. Typically, two sensors are applied to both sides of the forehead. The light passes not only through parts of the frontal brain, but also through the overlying skull and scalp. Contamination of the oximetry signal by extracranial blood sources is a serious concern, although the use of two sensing diodes with different distances from the light source within one sensor patch and adjustments of the algorithm of the oximeter may minimize this problem.[8,9]

Fig. 39.2 (A) Transcranial Doppler monitoring is done by insonating the arteries at the base of the brain through a thin part of the temporal bone. (B) If this procedure is performed with an imaging probe, some intracranial structures, such as the cerebral peduncles (white triangles) or the sella complex (white triangle labeled "S"), can be visualized. The captured Doppler signals originate from the right middle, right anterior, and left anterior cerebral arteries. (C) Normal Doppler spectrum obtained from the middle cerebral artery. By convention, flow toward the probe is displayed as a waveform above the baseline. (D) Doppler profile of the bifurcation of the terminal internal carotid artery as it branches into the middle cerebral artery (flowing toward the transducer) and the anterior cerebral artery (flowing away). This flow signal can be obtained if the transducer is focused as shown in A. (E–G) Examples of three clinical applications of transcranial Doppler. (E) Emboli are highly echogenic and appear as high-energy transient signals. On the audible output, these emboli are easily noticed as brief beeps or chirps. (F) Doppler profile of a middle cerebral artery in a patient with severe vasospasm after an aneurysmal subarachnoid hemorrhage (compare with C). (G) Transcranial Doppler examination consistent with intracranial circulatory arrest. There is a brief systolic inflow followed by retrograde flow during diastole.

Because 66% to 80% of the cerebral blood volume is venous blood, cerebral oximetry determines predominantly "local venous oxygen saturation." The simplicity of its use, and the familiarity with the principles of treating decreases in systemic mixed venous oxygen saturation, have made cerebral oximetry a popular trend monitor in operations that potentially cause decreases in blood flow to the vessels of the head.[10] There are some significant limitations, however, of the use of cerebral oximetry during such procedures. First, adequacy of global cerebral perfusion is inferred from measurements over the frontopolar brain. Second, normative data on normal values or expected changes for cerebral oximetry are largely absent, but preoperative application of the sensors allows the start of a trend in conjunction with a neurologic baseline examination.[11]

An example of how these limitations play out is provided by a study of the use of cerebral oximetry during 100 carotid endarterectomies in awake patients.[12] Cerebral oximetry was able to identify 97.4% of patients with adequate CBF as indicated by the absence of clinical symptoms. The monitor frequently indicated inadequate CBF, defined as a 20% decrease in cerebral oxygen saturation from the pre-clamp baseline, although the patient had no clinical symptoms of inadequate CBF. The false-positive rate of 66.7% may simply illustrate the fact that oxygen extraction increases before function fails. The real problem is that the lower limit for acceptable regional oxygen saturation is unknown in a large population of patients.[13] Acceptable values may be different from patient to patient, and addition of anesthetic drugs that influence cerebral metabolism may confuse the picture further.

Tissue-Level Blood Flow Monitoring Techniques (Invasive)

Tissue-level monitoring for the brain is by definition invasive. All monitors in current clinical or research use are implanted through a burr hole, extend either into the white matter or ventricular system, and typically use a bolt for stabilization. They all share a 1% to 2% risk of bleeding, infection, or ischemia owing to the implantation procedure.[14]

A second shared feature is their limited spatial resolution (i.e., each monitoring probe monitors only a limited area of brain surrounding the probe). When these monitors were first developed, there was considerable debate regarding the optimal placement of the device given such limited spatial resolution. Based on today's appreciation for the impact of secondary neurologic insults on the ultimate outcome, there is growing agreement that tissue-level monitoring is best performed in morphologically and functionally normal tissue that is part of the penumbra or vulnerable zone of interest.[15-17]

Of the tissue-level monitors, tissue partial pressure of oxygen (Po_2) monitoring has undergone sufficient refinement to be in wider clinical use. Thermal diffusion blood flow measurement and laser Doppler flow measurement are experimental and not in widespread clinical use.

Tissue Partial Pressure of Oxygen Monitoring

Localized monitoring of tissue Po_2 is based on an oxygen-sensitive electrode originally described by Clark.[18] The diffusion of oxygen molecules through an oxygen-permeable membrane into an electrolyte solution causes an electric current that is proportional to Po_2. Currently available catheter-based electrodes placed into the subcortical white matter provide stable recording conditions over long periods.

Most of the data on brain tissue oxygen levels ($P_{Br}o_2$) come from studies in patients with head trauma.[19] Comparison with stable xenon CT for assessment of CBF and studies during temporal clipping in aneurysm surgery show good correlation between $P_{Br}o_2$ and CBF.[20,21] Similarly, the time course of changes in $P_{Br}o_2$ after traumatic brain injury resembles that of CBF.[22,23] Critics of the technique argue that $P_{Br}o_2$ values are highly influenced by the partial pressure of arterial oxygen (Pao_2) and are merely an elaborate indicator of the quality of patient ventilation. This view is supported by the observation that increasing the fraction of inspired oxygen (Fio_2) increases $P_{Br}o_2$, but likely represents an oversimplification.[24] Concurrent microdialysis studies have shown that increasing Fio_2 not only increases $P_{Br}o_2$, but also decreases tissue lactate levels, suggesting a true improvement in the metabolic milieu of the brain tissue itself.[25,26] While decreases in $P_{Br}o_2$ are associated with worse outcomes in traumatic brain injury patients, the role of $P_{Br}o_2$-directed therapy is still investigational.[27]

MONITORS OF NERVOUS SYSTEM FUNCTION

The most commonly used monitors of function are the electroencephalogram (EEG), sensory-evoked responses (SERs), motor evoked responses, and the electromyogram (EMG). The EEG is a surface recording of the summation of excitatory and inhibitory postsynaptic potentials spontaneously generated by the pyramidal cells in the cerebral cortex. The signals are very small, and each recording electrode records information both directly beneath the electrode and information volume conducted from deeper tissue.[28] Monitoring the EEG is usually directed toward one or more of four perioperative uses. First, the EEG is used to help identify inadequate blood flow to the cerebral cortex caused by either a surgically induced or anesthetic-induced reduction in blood flow or retraction on cerebral tissue. Second, the EEG may be used to guide an anesthetic-induced reduction of cerebral metabolism either in anticipation of a loss of CBF or in the treatment of high intracranial pressure, when a reduction in CBF and blood volume is desired. Third, the EEG may be used to predict neurologic outcome after a brain insult. Finally, the EEG may be used to gauge the depth of the hypnotic state of the patient under general anesthesia (see Chapter 40).

More than 50 years of experience monitoring the EEG has led to many known correlations of EEG patterns with clinical states of the normal and diseased cerebral cortex. The electroencephalographer can accurately identify consciousness, unconsciousness, seizure activity, stages of sleep, and coma. In the absence of significant changes in anesthetic technique, the electroencephalographer also can accurately identify inadequate oxygen delivery to the brain (from either hypoxemia or ischemia). By using high-speed computerized EEG analysis and statistical methods, EEG patterns in the continuum from awake to deeply anesthetized are becoming, with few exceptions, much better understood. In addition, computer advances have made possible high-speed mathematic manipulation of the EEG signal to present the data in a manner more suitable to continuous trends for use during surgical or anesthetic monitoring.

Evoked potentials are electrical activity generated in response to either a sensory or a motor stimulus. Measurements of evoked responses may be made at multiple points along an involved nervous system pathway. The evoked responses are generally smaller than other electric activity generated in nearby tissue (muscle or brain) and are readily obscured by these other biologic signals. In the case of SERs, repeated sampling and sophisticated electronic summation and averaging techniques are needed to extract the desired evoked potential signal from background biologic signals. Motor-evoked responses are generally larger and commonly do not require averaging.

SERs are the most common type of evoked potentials monitored intraoperatively. During the last three decades, much research has been done on the use of intraoperative motor-evoked potentials (MEPs), and use of MEPs during both intracranial and spinal surgery is now no longer considered experimental. There are three basic types of SERs: somatosensory-evoked potentials (SSEPs), brainstem auditory-evoked potentials (BAEPs), and visual-evoked potentials (VEPs).

Electroencephalogram

Basic Unprocessed Electroencephalogram Concepts. The EEG is produced by a summation of excitatory and inhibitory postsynaptic potentials produced in cortical gray matter. Because the EEG signal is generated only by postsynaptic potentials and is much smaller than action potentials recorded over nerves or from heart muscle, extreme care must be taken when placing electrodes to ensure proper placement and excellent contact with the skin to avoid significant signal loss. Alternatively, subdermal needle electrodes may be used, particularly when sterile application of an electrode close to a surgical field is necessary. When electrodes are applied directly to the surface of the brain, impedance is minimized by close electrode contact and saturation of the area with an electrolyte solution.

EEG electrodes generally are placed according to a mapping system that relates surface head anatomy to underlying brain cortical regions. The placement pattern of recording electrodes is called a montage. Use of a standard recording montage permits anatomic localization of signals produced by the brain and allows development of normative EEG patterns and comparison of EEG recordings made at different times. The standard EEG "map" is called the 10 to 20 system for EEG electrode placement (Fig. 39.3). This system is a symmetric array of scalp electrodes placed systematically based on the distance from the nasion to the inion and from the pretragal bony indentations associated with both temporomandibular joints. Based on 10% or 20% of these distances, recording electrodes are placed systematically over the frontal (F), parietal (P), temporal (T), and occipital (O) regions at increasing distances from the midline. Left-sided electrodes are given odd number subscripts, and right-sided electrodes are given even number subscripts. Increasing numbers indicate a greater distance from the midline. Midline electrodes are designated with a "z" subscript. The standard diagnostic EEG uses at least 16 channels of information,[29] but intraoperative recordings have been reported using 1 to 32 discreet channels.

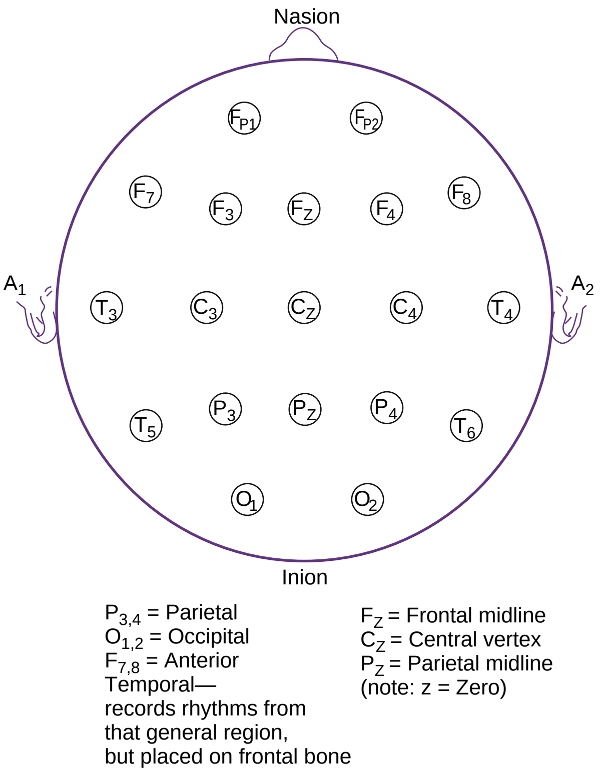

Fig. 39.3 International 10 to 20 system of electrode placement for recording electroencephalogram and sensory-evoked responses. (From Hughes JR. *EEG in Clinical Practice.* 2nd ed. Newton, MA: Butterworth-Heinemann; 1994.)

The intraoperative EEG is most commonly recorded from electrodes placed on the scalp. Recordings also may be made from electrodes placed on the surface of the brain (electrocorticography), or from microelectrodes placed transcortically to record from individual neurons (e.g., during surgery for Parkinson disease).[30,31] The EEG signal is described using three basic parameters: amplitude, frequency, and time. Amplitude is the size, or voltage, of the recorded signal and ranges commonly from 5 to 500 µV (vs. 1-2 mV for the electrocardiogram signal). Because neurons are irreversibly lost during the normal aging process, EEG amplitude decreases with age. Frequency can be thought of simply as the number of times per second the signal oscillates or crosses the zero voltage line. Time is the duration of the sampling of the signal; this is continuous and real time in the standard paper or digital EEG, but is a sampling epoch in the processed EEG (see later).

Normal Electroencephalogram. Normal patterns seen on the EEG vary among normal individuals, but are consistent enough to allow for accurate recognition of normal and pathologic patterns. The usual base frequency in an awake patient is the beta range (>13 Hz). This high-frequency and usually low-amplitude signal is common from an alert attentive brain and may be recorded from all regions. With eye closure, higher amplitude signals in the alpha frequency range (8-13 Hz), seen best in the occipital region, appear (Fig. 39.4). This "eyes closed" resting pattern is the

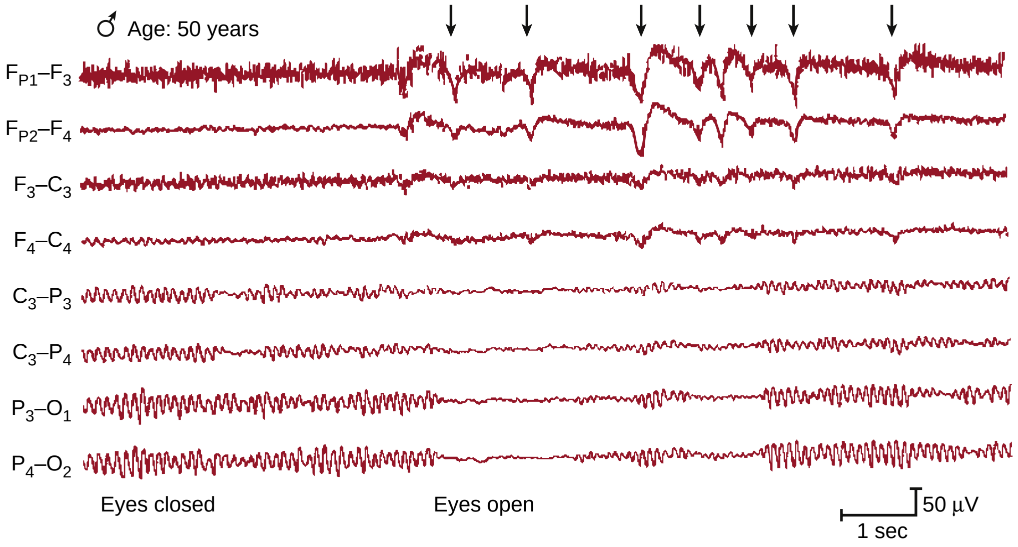

Fig. 39.4 The loss and return of alpha activity as the eyes open and close can be seen. The large spikes (↓) are muscle artifact from eye blinks and hence are best visible in channels that incorporate frontal electrodes (designated F).

baseline awake pattern used when anesthetic effects on the EEG are described. When events that lead the brain to produce higher frequencies and larger amplitudes occur, the EEG is described as "activated," and when slower frequencies are produced (theta = 4-7 Hz, and delta = <4 Hz), the EEG is said to be "depressed." The EEG during natural sleep may contain all of these frequencies at various times. The slower frequencies occur during deep natural sleep with "sleep spindles" (Fig. 39.5), but during light sleep or rapid eye movement sleep, the EEG becomes activated, and the eye muscle EMG appears on the EEG.

In the normal EEG in awake and asleep patients, patterns recorded from corresponding electrodes on each hemisphere are symmetric in terms of frequency and amplitude, the patterns are predictable if clinical states are known, and spike (epileptic) waveforms are absent. In most cases, normal EEG patterns are associated with normal underlying brain function in awake and asleep patients.

Abnormal Electroencephalogram. General characteristics of the "abnormal" EEG include asymmetry with respect to frequency, amplitude, or both, recorded from corresponding electrodes on each hemisphere, and patterns of amplitude and frequency that are unpredictable or unexpected in the normal recording. These abnormal patterns reflect either anatomic or metabolic alterations in the underlying brain. Regional asymmetry can be seen with tumors, epilepsy, and cerebral ischemia or infarction. Epilepsy may be recognized by high-voltage spike and slow waves, whereas cerebral ischemia manifests first with EEG slowing with preservation of voltage. Further slowing and loss of voltage occurs as ischemia becomes more severe. Factors affecting the entire brain may produce symmetric abnormalities of the signal. Identifying pathologic abnormal patterns in the global EEG signal is very important, although sometimes quite difficult, in the clinical situation. Many of the normal global pattern changes produced by anesthetic drugs are similar to pathologic patterns produced by ischemia or hypoxemia. Control of anesthetic technique is very important when the EEG is being used for clinical monitoring of the nervous system.

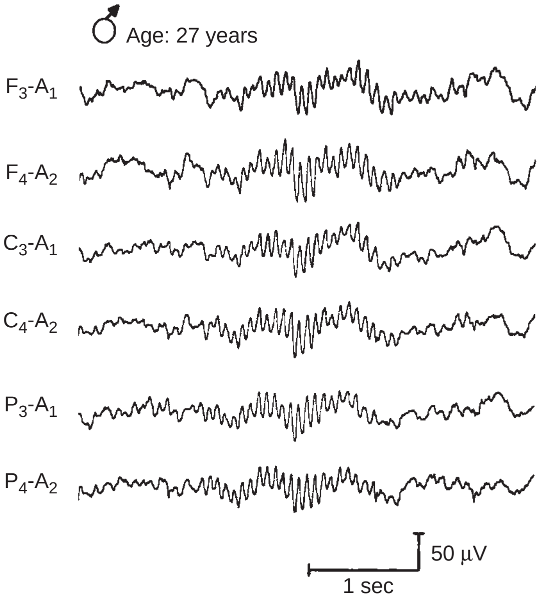

Fig. 39.5 Characteristic sleep spindles in normal sleep are shown in the center.

Processed Electroencephalogram Concepts. Numerous limitations are introduced when moving from the raw EEG domain to the processed EEG domain. First, artifact is processed in many cases along with desired signal leading to a perfectly believable processed EEG display that is materially incorrect. Second, the standard 16-channel EEG montage provides more information than can be practically analyzed or displayed by most processed EEG monitors and perhaps more than is needed for routine intraoperative use. Most available processed EEG devices used by anesthesiologists use four or fewer channels of information—translating to at most two channels per hemisphere. Processed EEG devices generally monitor less cerebral territory than a standard 16-channel EEG. Third, some intraoperative changes are unilateral (e.g., regional ischemia owing to carotid clamping), and some are bilateral (e.g., EEG depression by bolus administration of an anesthetic). Display of the activity of both hemispheres is necessary to delineate unilateral from bilateral changes. An appropriate number of leads over both hemispheres is needed. Most early studies validating intraoperative EEG monitoring used continuous visual inspection of a 16- to 32-channel analog EEG by an experienced electroencephalographer—such monitoring was considered the gold standard.[32,33] Adequate studies comparing the processed EEG with fewer channels with this gold standard across multiple uses and operations have not been done, although limited data using processed EEG monitoring during carotid surgery suggest that two- or four-channel instruments would detect most significant changes,[34,35] provided that the electrodes are appropriately placed over watershed areas of blood supply.

Devices. EEG processing for intraoperative monitoring is typically based on power analysis of a segment of raw EEG, referred to as an epoch. Power analysis uses Fourier transformation to convert the digitized raw EEG signal into component sine waves of identifiable frequency and amplitude. The raw EEG data, which is a plot of voltage versus time, is converted to a plot of frequency and amplitude versus time. Many commercially available processed EEG machines display power (voltage or amplitude squared) as a function of frequency and time. These monitors display the data in two general forms, either compressed spectral array or density spectral array. In compressed spectral array, frequency is displayed along the x axis, and power is displayed along the y axis with height of the waveform equal to the power at that frequency. Time is displayed along the z axis. Tracings overlap each other, with the most recent information in front (Fig. 39.6). Density spectral array also displays frequency along the x axis, time is displayed along the y axis, and power is reflected either by the density of the dots at each frequency or by a spectrum of colors. Each display format provides the same data, and choice depends on the preference of the user.

Many changes that occur during anesthesia and surgery are reflected as changes in amplitude, frequency, or both. These changes can be clearly seen in these displays if adequate and appropriate channels are monitored. Power

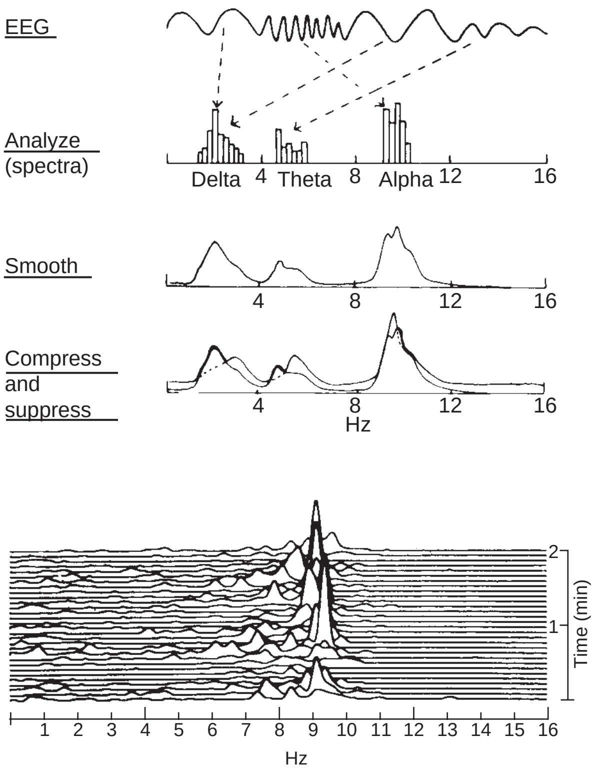

Fig. 39.6 Diagram of a technique used to generate compressed spectral array. Example at the bottom of the figure shows compressed spectra of the alpha rhythm from a normal subject. *EEG*, Electroencephalogram. (From Stockard JJ, Bickford RG. The neurophysiology of anaesthesia. In: Gordon E, ed. *A Basis and Practice of Neuroanesthesia*. New York: Elsevier; 1981:3.)

analysis has been used clinically for many years as a diagnostic tool during procedures with risk for intraoperative cerebral ischemia, such as carotid endarterectomy and cardiopulmonary bypass (CPB). Power analysis has proven to be a sensitive and reliable monitor in the hands of experienced operators using an adequate number of channels. In addition, parameters obtained from power analysis have been investigated as monitors for depth of anesthesia.[36-39]

Data Acquisition Period. An important consideration in the processed EEG is time. Raw EEG is continuous in real time. The processed EEG samples data over a given time period (epoch), processes the data, and then displays information in various formats. There is a relationship between epoch length and spectral resolution. If a long epoch length is chosen, the waveform can be described precisely, but the time required for data processing is long and not real time. If a short length of data is sampled, analysis may be done in near real time, but the epoch chosen for analysis may not be representative of the overall waveform (i.e., the condition of the patient). There also may be insufficient data points for meaningful Fourier transformation. This issue, as related to the use of intraoperative EEG for analysis of anesthetic depth, has been studied by Levy.[40] A longer epoch may produce less epoch-to-epoch variability and allow more precise description of frequency and power; however, the longer epoch increases the delay before new information is processed and displayed, reducing the amount and timeliness of information available for clinical decision making. In studying EEG epochs of 2 to 32 seconds, Levy[40] concluded that 2-second epochs are appropriate during general anesthesia. Many commercially available devices have used 2-second epoch lengths, updated at varying user-selected intervals. With better and faster computers, continuous monitoring of 2-second epochs and now even longer epochs is possible.

Evoked Potentials

Basic Concepts Common to All Modalities. EEG signals provide information about cortical function, but little to no information about subcortical neural pathways crucial to normal neurologic function. Intraoperative monitoring of SERs has gained increasing popularity over the last 35 years because it provides the ability to monitor the functional integrity of sensory pathways in an anesthetized patient undergoing surgical procedures placing these pathways at risk. Because motor pathways are often adjacent anatomically to these sensory pathways or supplied by the same blood vessels, or both, function of motor pathways may be inferred, albeit imperfectly, from the function of these sensory pathways. Today, MEPs are monitored together with SERs to provide direct information about function of motor pathways. SERs are typically 100-fold smaller in amplitude than the EEG. Recording SERs in an environment such as an operating room with its myriad electrical devices is challenging and requires substantial technical expertise.

Sensory-Evoked Responses. SERs are electric CNS responses to electric, auditory, or visual stimuli. SERs are produced by stimulating a sensory system and recording the resulting electric responses at various sites along the sensory pathway up to and including the cerebral cortex. Because of the very low amplitude of SERs (0.1-10 μV), it is often impossible to distinguish SERs from other background biologic signals, such as the EEG or EMG, which may be considered in this case undesirable "noise." To extract the SER from the background noise, the recorded signal is digitized, and signal averaging is applied. With this technique, signal recording is time-locked to the application of the sensory stimulus. For example, during intraoperative posterior tibial nerve SER monitoring, after nerve stimulation at the ankle, only signal information occurring less than 90 ms after the stimulus is recorded (Fig. 39.7). The SER occurs at a constant time after the stimulus application; other electric activity, such as spontaneous EEG, occurs at random intervals after the sensory stimulus. The averaging technique improves the SER signal-to-noise ratio by eliminating random elements and enhancing the SER. This enhancing effect increases directly with the square root of the number of responses added into the averaged response.

SER recordings are of two general types determined by the distance of the recording electrode from the neural generator of the evoked response. SERs recorded from electrodes close to the neural generators (within approximately 3-4 cm in the average adult) are termed "near-field potentials."[41] Near-field potentials are recorded from electrodes placed very close to the actual signal generator site,[42] and the morphology is directly affected by electrode location.[41] Far-field potentials are recorded from electrodes located a greater distance from the neural generator and are conducted to the recording electrode through a volume

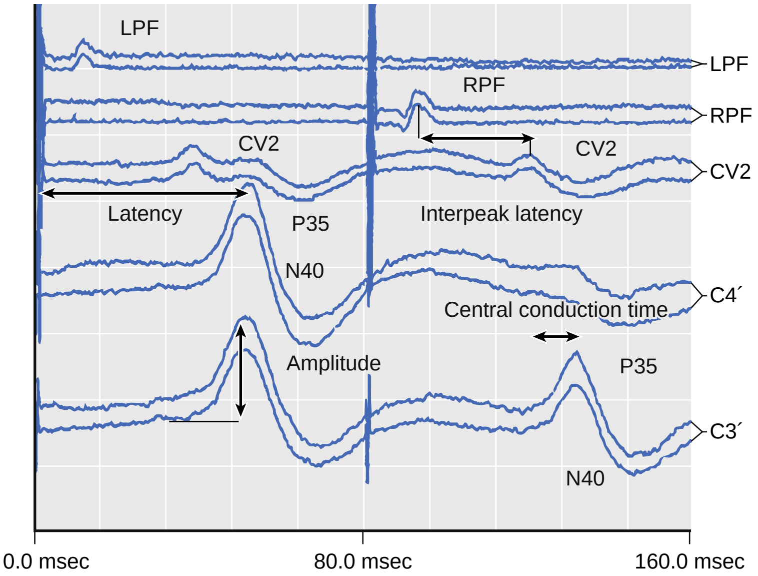

Fig. 39.7 Sensory-evoked responses are described in terms of latency and amplitude. Interpeak latency is the measured time between two peaks. Interpeak latency may be measured between two peaks in the same channel or between peaks in different channels (shown in figure). Note that the polarity of peaks is displayed contrary to standard convention (see text). The example shows a recording of posterior tibial somatosensory-evoked potentials. Each tracing is reproduced twice because reproducibility of a waveform helps distinguish signal from artefact. Left and right posterior tibial nerves are stimulated at 0 and 90 ms, respectively. The first evoked response is recorded from left and right popliteal fossa (*LPF* and *RPF*, respectively). The peak labeled CV2 represents the brainstem response recorded at the craniocervical junction. As a far-field potential, the potential looks similar for right- and left-sided stimulation. The primary cortical responses are recorded from the contralateral hemisphere (labeled P35 and N40).

conductor (brain, cerebrospinal fluid, and membranes). Because the current spreads diffusely throughout the conducting medium, it is more difficult to locate the source of the recorded signal and the electrode position has little effect on the morphology of the recorded evoked potential (see Fig. 39.7).[41,42] As the distance between the recording electrode and the neural generator increases, the recorded SER becomes smaller. More responses have to be averaged to record far-field potentials (several thousand) than near-field potentials (50–100).[41,42]

SERs also may be described as cortical or subcortical in origin. Cortical SERs are generated by the arrival at the cortex of the volley of action potentials generated by stimulating the sensory system. Because they are recorded as a near-field potential, they are typically easy to identify by elapsed time, waveform morphology, and amplitude. Subcortical responses may arise from many different structures depending on the type of response, including peripheral nerves, spinal cord, brainstem, thalamus, cranial nerves, and others. Cortical SERs are usually recorded from scalp electrodes placed according to the standard 10 to 20 system for EEG recordings (see Fig. 39.3). Subcortical evoked responses also may be recorded as far-field potentials from scalp electrodes or, as appropriate, from electrodes placed over the spinal column or peripheral nerve.

Evoked potentials of all types (sensory or motor) are described in terms of latency and amplitude (see Fig. 39.7). Latency is defined as the time measured from the application of the stimulus to the onset or peak (depending on convention used) of the response. The amplitude is simply the voltage of the recorded response. According to convention, deflections below the baseline are labeled “positive (P),” and deflections above the baseline are labeled “negative (N).” Because amplitude and latency change with recording circumstances, normal values must be established for each neurologic monitoring laboratory, and may differ from values recorded in other laboratories.

SERs used for intraoperative monitoring include SSEPs, BAEPs, and rarely VEPs. For all these techniques, cortical recording electrodes are placed on the scalp, using the same standard 10 to 20 system as for recording the EEG, whereas recordings for subcortical and peripheral signals are placed in various standardized anatomic locations. The surgical incision and the need for sterility may necessitate nonstandard electrode placements. Such deviations must be considered when interpreting baseline and subsequent SERs. In the case of MEPs, stimulating electrodes also are placed according to the 10 to 20 system of electrode placement, but over the motor cortex instead. Recording electrodes may be placed over the spinal column, peripheral nerve, and (most commonly) innervated muscle.

One of the most important principles of recording SERs intraoperatively is that reproducible, reliable tracings must be obtained at baseline before any intervention likely to cause changes in the evoked response. If good-quality tracings with identifiable waveforms cannot be recorded and reproduced at baseline, evoked-response monitoring would be of little use in monitoring the integrity of the CNS intraoperatively. If significant variability exists, or waveforms are difficult to identify, it will be impossible intraoperatively to distinguish SER changes that are clinically significant from a preexisting baseline variability of waveforms. When good, reproducible responses cannot be recorded at baseline, monitoring should not be used for clinical decision making. It is helpful to comment on the quality of the baseline SERs during the preincision time out so that the whole team is better positioned to put changes in SERs into context.

Somatosensory-Evoked Potentials. SSEPs are recorded after electric stimulation of a peripheral mixed nerve using needles or surface gel electrodes. SSEP responses consist of short-latency and long-latency waveforms. Cortical short-latency SSEPs are most commonly recorded intraoperatively because they are less influenced by changes in anesthetic drug levels. The pathways involved in the generation of upper extremity short-latency SSEPs include large-fiber sensory nerves with their cell bodies in the dorsal root ganglia and central processes traveling rostrally in the ipsilateral posterior column of the spinal cord synapsing in the dorsal column nuclei at the cervicomedullary junction (first-order fibers), second-order fibers crossing and traveling to the contralateral thalamus through the medial lemniscus, and third-order fibers from the thalamus to the frontoparietal sensorimotor cortex. These primary cortical-evoked responses, which are recordable with most anesthetic techniques, result from the earliest electric activity generated by the cortical neurons and are thought to arise from the postcentral sulcus parietal neurons. The longer-latency secondary cortical waves are thought to arise in the association cortex. These responses have much greater variability in an awake patient,[42] habituate rapidly on repetitive stimulation,[41] and are only poorly reproducible during general anesthesia. Cortical SSEPs other than the primary cortical response are not monitored or interpreted intraoperatively because they are severely altered by general anesthesia.[41]

Although most evidence indicates that upper extremity evoked potentials are conducted rostrally in the spinal cord through dorsal column pathways, some data suggest that lower extremity SSEPs are conducted at least partially by the lateral funiculus.[43] Stimulation of the posterior tibial nerve or common peroneal nerve at or above motor threshold activates group I fibers that synapse and travel rostrally through the dorsal spinocerebellar tract. After synapsing in nucleus Z at the spinomedullary junction, the pathway crosses and projects onto the ventral posterolateral thalamic nucleus.[44] This pathway difference is important because the dorsal lateral funiculus is supplied primarily by the anterior spinal artery, the artery that also supplies the descending motor pathway and neurons in the spinal cord. Manipulations, such as distraction of the spinal column to correct scoliosis, which may secondarily compress or distort radicular blood supply to the anterior spinal cord, should cause changes in the SSEP in the event blood supply is reduced to critical levels. This hypothesis is verified by the very low, but not zero, incidence of postoperative paraplegia on awakening without any intraoperative changes in SSEPs.

For SSEP recordings with median nerve stimulation, recording electrodes are first placed at Erb point, just above the midpoint of the clavicle. This point overlies the brachial plexus, and signals recorded here assure the clinician that the stimulus is actually being delivered properly to the patient. The next electrode is placed midline posteriorly over the neck at level of the second cervical vertebra, relatively near the dorsal column nuclei. Signals recorded here ensure proper transmission of the response from the peripheral nervous system into the spinal cord and rostral along the spinal cord to the lower medulla. The final electrodes are placed on the scalp overlying the sensory (parietal) cortex contralateral to the stimulated limb. Signals recorded here ensure the integrity of the pathway through the brainstem, thalamus, and internal capsule, and may assess adequacy of CBF in this area of the cortex.[45-49]

TABLE 39.1 Generators of Somatosensory-Evoked Potentials After Median Nerve Stimulation

Peak	Generators
N9 (EP)	Brachial plexus*
N11	Posterior columns or spinal roots
N13/P13	Dorsal column nuclei*
N14, 15	Brainstem or thalamus
N19/P22	Parietal sensory cortex*

*Indicates sites commonly recorded during surgical procedures. All other waveforms indicated are not commonly monitored.

To record SSEPs after posterior tibial nerve stimulation, electrodes are placed first over the popliteal fossa to ensure proper stimulus delivery to the nervous system. Electrodes also may be placed over the lower lumbar spine to ensure proper transmission of the signal into the spinal cord itself, but this site is not commonly used because of the proximity of sterile surgical incisions. Cervical spine and scalp recording electrodes are placed in a similar fashion as described previously, although different locations may be used as required by the surgical incision. More invasive recording methods, such as epidural electrodes, also may be used intraoperatively.

Purported generators for short-latency SSEPs are listed in Table 39.1 and shown in Fig. 39.8.[41,50] Induction of anesthesia, a patient's neurological disease or age, and use of different recording electrode locations (montage), necessitated by the surgical incision, may significantly alter the appearance of the SSEP. In these cases, attribution of a particular generator to a given wave on the tracing may be quite difficult. During neurologic monitoring, such precision is not needed, and recorded waveforms are compared with tracings obtained at baseline and during earlier portions of the surgical procedure. After lower limb stimulation, absolute latencies are increased because of the greater distance the response to stimulation must travel along the peripheral sensory nerve and spinal cord. Interpeak latencies (see Fig. 39.7) also are evaluated to assess specific conduction times, such as N9 to N14 conduction time, reflecting transmission time from the brachial plexus to brainstem, or N14 to N20 conduction time, reflecting transmission time between the dorsal column nuclei and the primary sensory cortex.[51] Latencies are also significantly affected by age at both extremes of life and many neurologic disorders.

Brainstem Auditory-Evoked Potentials. BAEPs are produced in the diagnostic laboratory by delivering repetitive clicks or tones via headphones. Headphones are not practical for surgical monitoring of neurosurgical procedures, and click stimuli are delivered using foam ear inserts attached to stimulus transducers (Fig. 39.9). Stimulus intensity is usually set at 60 to 70 dB above the patient's click-hearing threshold, although, practically speaking, many intraoperative laboratories establish monitoring after induction of anesthesia and instead begin with a stimulus

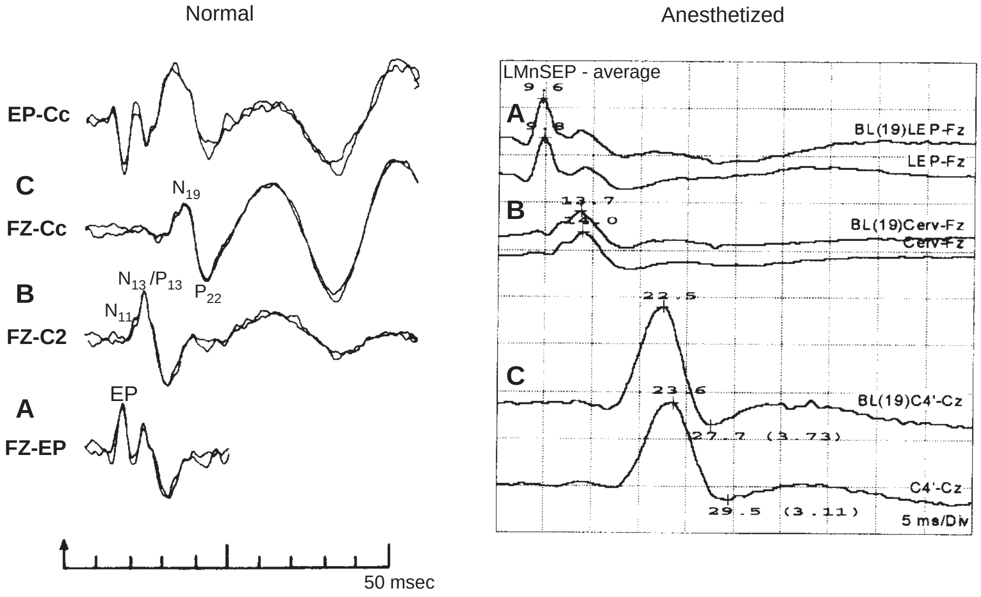

Fig. 39.8 Short-latency somatosensory-evoked potentials *(SEP)* produced by stimulation of the left median nerve *(LMn)* at the wrist. The ability to identify each of the labeled peaks shown in the tracing from the awake patient is compromised by the anesthetic state and use of different recording electrode locations (A–C). Corresponding tracings are labeled with the same letter. (From Chiappa KH, Ropper AH. Evoked potentials in clinical medicine. *N Engl J Med*. 1982;306:1205.)

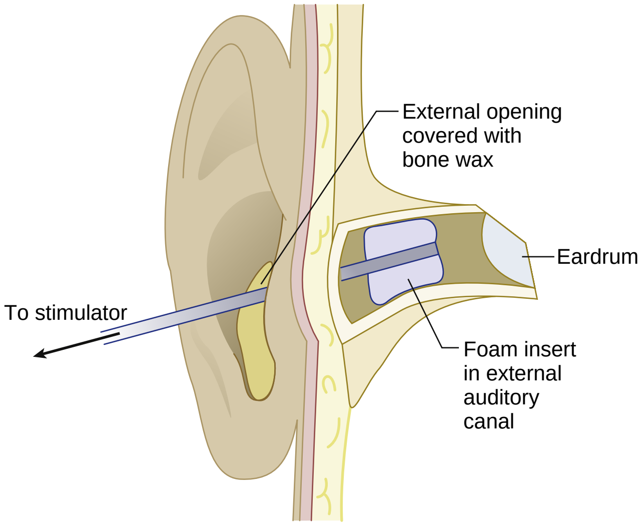

Fig. 39.9 Schematic of brainstem auditory-evoked potential-stimulating apparatus. Loud click stimuli are delivered directly to the eardrum through the ear insert.

intensity of 90 dB nHL (normal hearing level). The duration of the click is approximately 100 µs, and the stimulus is given usually 10 to 15 times per second. Clicks are delivered using different "polarities"—that is, the click may cause initial movement of the tympanic membrane away from the transducer (rarefaction) or toward the transducer (condensation). Use of these two different methods commonly produces very different waveforms, amplitudes, and latencies in individual patients, and the method that produces the largest reproducible response is chosen. If stimulus artifact is a serious problem, clicks of alternating polarity may be used to decrease the artifact, but the waveforms produced are an average of those produced by either stimulating technique alone and may be more difficult to monitor.

Rate and intensity of stimulus delivery affect BAEPs.[41,52] Unilateral stimulation is used because responses from the other ear, which may remain normal during surgery, may obscure any abnormal responses from the monitored ear. Recording electrodes are placed on the lobe of the stimulated ear and on the top of the head (vertex).[52] White noise may be delivered to the contralateral ear to prevent bone conduction from stimulation of the monitored ear from producing an evoked response from the contralateral ear. On average, 500 to 2000 repetitions are required because BAEPs recorded from the scalp are far-field potentials and extremely small (often $<0.3\ \mu V$).[41,52]

Peaks in recordings of BAEPs are labeled I through VII; the purported neural generators for these peaks and the auditory pathway are shown in Fig. 39.10. The anatomic auditory pathway would predict that BAEP monitoring would be most useful for surgical procedures in the posterior fossa that risk hearing or structures in the upper medulla, pons, and midbrain. As with other SERs, amplitude, absolute latencies, and interpeak latencies are evaluated to assess integrity of the auditory system, localize the functional defect when it occurs, and assess peripheral and central conduction times. Because waves VI and VII are inconsistent and variable, they are not routinely monitored,[52] and most articles reporting use of BAEP for surgical monitoring in the operating room monitor waves only up to wave V.[53-55]

Visual-Evoked Potentials. VEPs are recorded after monocular stimulation with recording electrodes over the occipital, parietal, and central scalp.[56] Flash stimulation of the retina using light-emitting diodes embedded in soft plastic goggles through closed eyelids or as needed via contact lenses with built-in light-emitting diodes is provided. VEPs are cortical SERs, which vary with the type of stimulus, part of the retina stimulated, degree of pupil

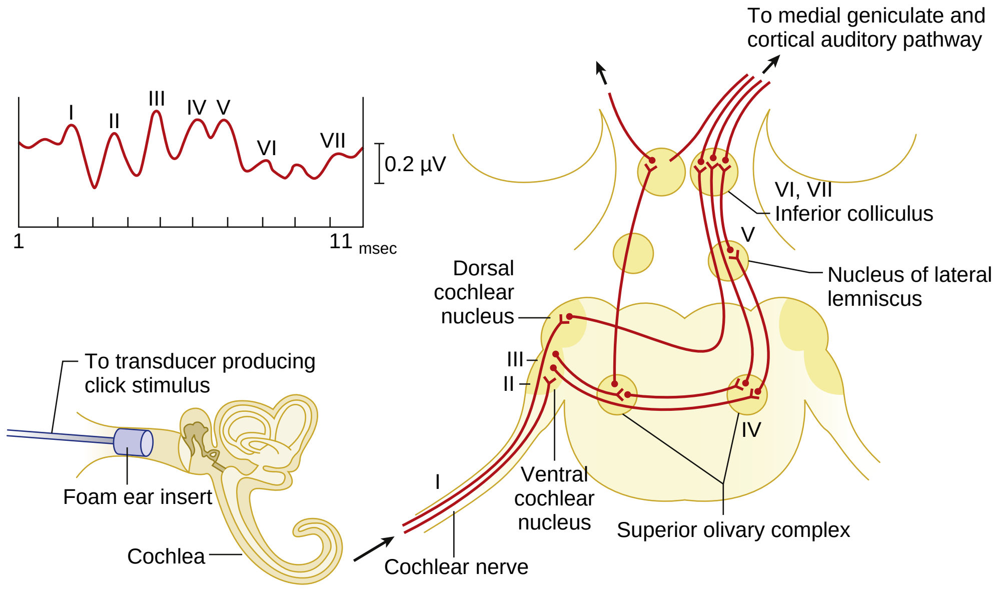

Fig. 39.10 Schematic of auditory neural pathway. The brainstem auditory-evoked potential is initiated by stimulation of the cochlea with a broadband click stimulus given through an ear insert in the external auditory canal. Neural generators of the brainstem auditory-evoked potential peaks are shown.

dilation, and patient's attention level.[41] Because some of these factors change commonly and even constantly during the course of every anesthetic, VEPs would be expected to be highly variable during surgery even when no surgical trespass on the visual system occurs. VEPs are the least commonly used evoked-response monitoring technique intraoperatively. However, some investigators have recently been able to generate reproducible intraoperative VEPs using multiple red light-emitting diodes embedded in a soft silicone disk placed directly on the cornea for stimulating the retina.[56] This technique may allow for further studies which will determine the clinical utility of this modality. However, flash stimuli generate potentials in all areas of the primary visual cortex at once making it difficult detect an injury to a small area of cortex.

Motor-Evoked Potentials. MEPs are generated most commonly by the application of a transcranial train of electric stimuli, and responses are recorded at various points along the spinal column, peripheral nerve, and innervated muscle.

Transcranial Motor-Evoked Potentials. Monitoring of the integrity of the motor tracts within the spinal cord is a technique with great potential benefit, and even during the relative short history of MEP monitoring, there are reported cases of loss of MEPs with preservation of the SSEP.[57-62] This technique is used extensively in spinal surgery, in which transmission across the operative field can be assessed, and in aortic surgery, with the potential for impairment of the blood supply to the vulnerable anterior spinal cord. Relative to SER monitoring, MEP monitoring is quite invasive and, in the case of transcranial stimulation, uses much higher stimulus intensity (≥400 V). Special stimulation techniques may be used to obtain transcranial MEPs (tcMEPs) from young children or adults with some degree of neurologic compromise at baseline.

Several variants of MEP monitoring exist. The most common method involves transcranial electrical stimulation. During transcranial electric MEP monitoring, stimulating electrodes (usually small, metallic screw-type electrodes similar to those used in fetal monitoring) are placed into the scalp overlying the motor cortex, and a train of electric stimuli (usually around 400–500 V) is applied to the scalp. This stimulation definitely activates muscles of mastication, and bilateral bite-blocks must be placed to prevent serious damage to the tongue during stimulation. Alternatively, if the precentral gyrus or motor strip is exposed during surgery, stimulating electrodes may be placed directly onto the cortex. Because approximately 90% of the transcranial stimulus dissipates across scalp and skull, typical stimulus intensities of direct cortical stimulation are 40 to 50 V.

Both stimulating methods also activate surrounding cortical structures and subcortical white matter pathways (sensory and motor). In fact, tcMEPs can frequently be recorded from patients with cerebral palsy, despite the disruption of their cortical neuronal architecture. Distal antidromic propagation of the transcranially applied stimulus is blocked by synapses in all of the ascending sensory pathways. The stimulus is propagated easily orthodromically through descending motor pathways. It is important to note that only the largest diameter fibers, 2% to 3% of all fibers in the corticospinal tract, propagate the impulses associated with tcMEPs. The evoked responses may be recorded over the spinal cord, the peripheral nerve, and, most commonly, the muscle itself. To enhance the MEP, these responses may be averaged in the same manner as SERs, but averaging is almost always unnecessary. Activation of the corticospinal tract well below the motor cortex may limit the utility of tcMEP to assess the adequacy of CBF to the motor cortex, because activation may be distal to the site of ischemia and part of a different vascular bed.

Electromyography. Intraoperative monitoring of EMG responses generated by cranial and peripheral motor nerves allows early detection of surgically induced nerve damage and assessment of level of nerve function intraoperatively. In these cases, the ability of a nerve to produce a response in the innervated muscle is used to assess the health of a cranial or peripheral nerve at risk during surgery. Recordings are made from either surface (electrocardiogram or gold cup) electrodes or needle electrodes placed directly in the innervated muscle of interest. Sensitivity of EMG recordings is best if recordings are made from needles within the muscle itself. Surface electrodes and, to a lesser extent, subdermal needle electrodes may completely miss neurotonic discharges that indicate damage to a nerve.[63] The most experience with this monitoring modality has been obtained during facial nerve monitoring.

EMG monitoring may be either active or passive. During active monitoring, a cranial or peripheral nerve is stimulated electrically, and the evoked EMG (compound muscle action potential) response from the muscle is recorded. Stimulation of the nerve proximal to the operative area or tumor can be used to assess functional integrity of the nerve.[64] Nerve function also may be assessed by noting the intensity of nerve stimulus needed to evoke a muscle response and by the morphology of the compound muscle action potential. Nerve function may be monitored passively during surgery with continuous recording of all generated responses from innervated muscle groups. “Popcorn” EMG discharges are produced by simple, benign contact with the monitored nerve. Response trains are produced with more significant nerve irritation. Neurotonic discharges are produced by significant nerve irritation or damage or both (Fig. 39.11).[65] When these EMG responses reach a certain voltage threshold, they are usually converted into audible signals that provide immediate feedback to the surgeon and warn of impending nerve damage in real time. Real-time feedback is key because density and frequency of neurotonic discharges may correlate with degree of postoperative nerve dysfunction, as shown by data obtained from patients undergoing resection of acoustic tumors.[64] One caveat of EMG monitoring is that sharp section of a nerve may produce no EMG discharge at all.

Intraoperative monitoring of the motor component of other cranial nerves also has been successfully performed. EMG monitoring of the trigeminal nerve can be accomplished with electrodes placed over or in the temporalis or masseter muscles. Trigeminal nerve motor monitoring has been used during nerve section for tic douloureux to ensure preservation of the motor branch of the trigeminal nerve and in combination with facial nerve monitoring during resection of large posterior fossa lesions.[65] Using recording electrodes placed in or over the trapezius or sternocleidomastoid muscles, the spinal accessory nerve has been successfully monitored during resection of large meningiomas, glomus jugulare tumors, and neck carcinomas.[65] EMG monitoring of the hypoglossal nerve with needle electrodes placed in the tongue has been infrequently used for large posterior fossa lesions and clivus tumors.[65] EMG monitoring of the eye muscles can be performed using tiny hook wires for recording; however it is rarely used in practice.

Monitoring of peripheral motor nerves has been performed by placing needle electrodes in or over the muscles innervated by nerves that traverse the operative area and are at risk from the planned surgical procedure. Auditory feedback from EMG monitoring can warn the surgeon of unexpected surgical trespass of the nerve, help locate a nerve within the field (e.g., during untethering of the spinal cord), and localize the level of any conduction block or delay. Because radiculopathies have been reported to occur after spine surgery, particularly because of incorrect pedicle screw placement, EMG monitoring of peripheral nerves has been used in patients undergoing spine surgery to decrease the risk of nerve root injury during the procedure.[65] During pedicle screw placement, the surgeon can stimulate the screw directly with a small amount of current. If EMG responses are produced with only a small amount of current, the screw has likely been placed outside the bony pedicle.

Reactions to Intraoperative Changes in Monitored Responses

Intraoperative changes in evoked responses, such as decreased amplitude, increased latency, or complete loss of the waveform, may result from surgical trespass, such as retractor placement or ischemia, or they may reflect systemic changes, such as changes in anesthetic drug administration, temperature changes, or hypoperfusion. When these changes are detected and considered to be significant, the surgeon or anesthesiologist can make changes to relieve or lessen the insult to the monitored pathway (and presumably surrounding neural structures). Interventions by the anesthesiologist are directed at improving perfusion to the nervous tissue at risk and include increasing arterial blood pressure, especially if induced hypotension is used, or if the patient’s blood pressure has decreased significantly from preoperative values; transfusion, if significant anemia is present; volume expansion; augmentation of cardiac output; and normalization of abnormal arterial blood gas tensions. Changes in evoked potentials after retractor

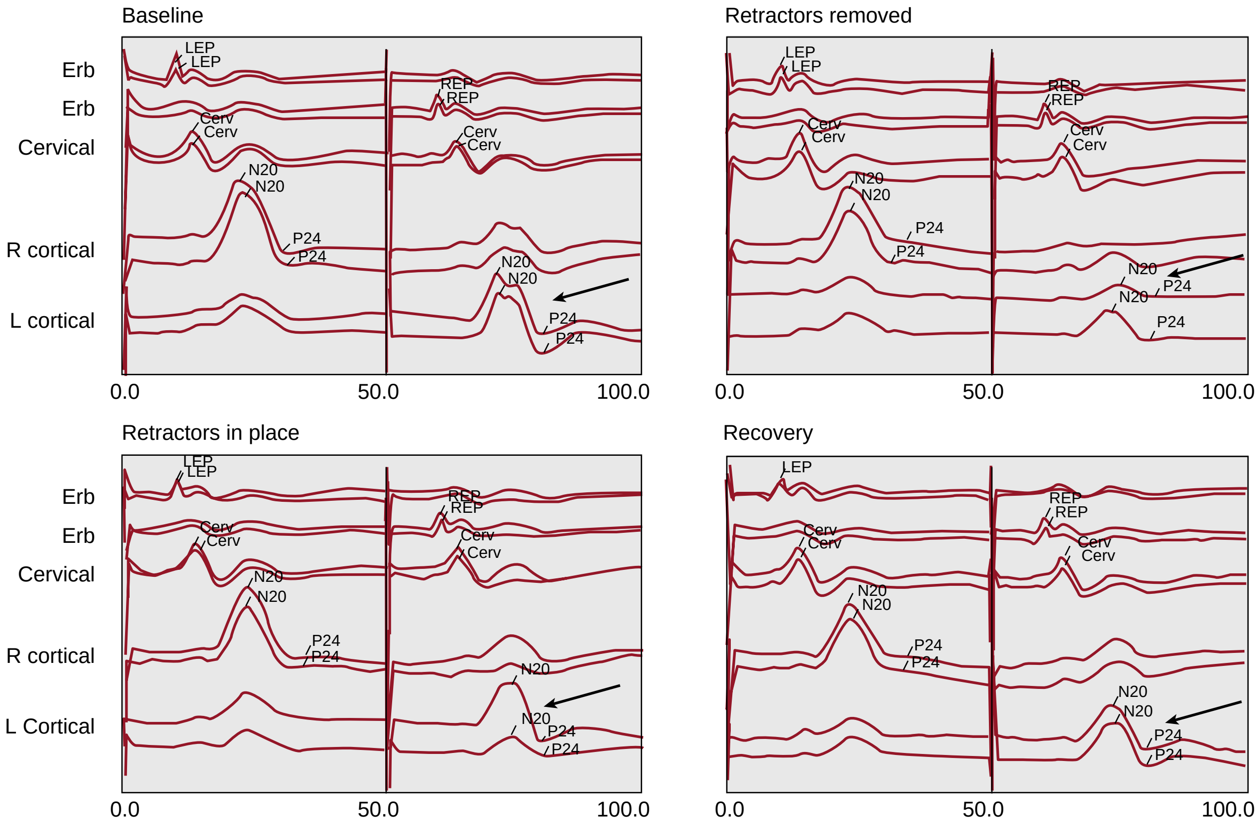

Fig. 39.12 Somatosensory-evoked potentials during aneurysm clipping. Responses generated by the cortex at risk are indicated by arrows. Baseline, after retractor placement, after retractor removal, and recovery traces are shown. The initial evoked response change occurred 4 minutes after retractor placement. Note loss of voltage of cortical-evoked response caused by inadvertent compression of the middle cerebral artery. *Cerv,* Cervical; *LEP,* left Erb point; *REP,* right Erb point.

placement during a craniotomy or after compression of the blood supply to the spinal cord from spinal column distraction promptly allow the surgeon and the anesthesiologist to make appropriate changes to the operative procedure and anesthetic management that may prevent or minimize any postoperative neurologic deficit (Fig. 39.12). It is imperative that clear communication occur between all parties in the operating room when significant intraoperative changes in evoked potentials occur. If expected results of an intervention are not observed the underlying hypothesis as to the cause of the changes must be reevaluated. This can only happen when lines of communication are open between all participants.[66]

Tolerance limits for degree of change in evoked response signals or duration of complete loss of waveform before permanent neurologic dysfunction are becoming better defined, and position statements have been issued by the American Society of Neurophysiologic Monitoring (http://www.asnm.org/page/PositionStatements). Tolerance limits for degree of change are especially unclear for tcMEPs. Such ambiguity is common among intraoperative monitors. Although we do know that increased frequency and duration of ST segment depression during coronary bypass surgery is associated with an increased risk of perioperative infarction, exact limits for degree and duration of ST segment depression for surgery do not exist, and likely vary significantly from patient to patient. The same problem may be exhibited with neurologic monitors.

Many centers using intraoperative SER monitoring define decreases in amplitude of 50% or more from baseline associated with a less than 10% prolongation in latency as clinically significant SER changes. Uncorrected, such changes are associated in clinical series and in case reports with onset of new postoperative neurologic deficits. As a result, such changes are immediately investigated. In practice, any SER changes directly associated with a surgical event are considered clinically significant, however, even if the magnitude of change is less than just described. Changes in SER that do not progress to complete loss of the waveform are less likely to be associated with a major new postoperative neurologic deficit. Complete loss of the SER waveform intraoperatively without recovery is highly likely to be associated with a major new deficit. If the SER recovers either spontaneously or after intraoperative interventions, the likelihood of neurologic injury depends on the procedure, the duration of the SER loss, and on whether the SER is mainly used to judge integrity of adjacent unmonitored structures. These problems are illustrated in one study of intracranial aneurysm surgery in which SSEPs were monitored to predict/prevent postoperative motor deficits. Loss of the SSEP waveform for less than 15 minutes was not associated with a new permanent neurologic deficit, whereas complete loss of the SSEP for longer periods was increasingly likely to reflect permanent neurologic injury, even if the response recovered completely to its intraoperative baseline during surgery.[67]

Clinical Applications of Neurologic Monitoring

NEUROVASCULAR SURGERY (ALSO SEE CHAPTERS 56 AND 57)

Extracranial Neurovascular Surgery: Carotid Vascular Surgery (Monitors: Electroencephalogram, Somatosensory-Evoked Potentials, Transcranial Doppler, Cerebral Oximetry)

Carotid vascular surgery typically requires transient interruption of blood flow to the brain through the affected carotid artery. Although the risk of stroke associated with carotid vascular surgery has been declining,[68] the residual risk varies greatly based on the indication for the procedure. It is lowest for asymptomatic patients and highest after a recent revascularization for ischemic stroke.[69]

Electroencephalogram. The use of the EEG as a monitor of the adequacy of hemispheric blood flow during carotid endarterectomy has been established for many years. In a large series of patients undergoing carotid endarterectomy at the Mayo Clinic,[33] the EEG was compared with regional CBF using the Xe washout method. This study validated the EEG as an indicator of the adequacy of regional CBF.

Normal CBF in gray and white matter averages 50 mL/100 g/min. With most anesthetic techniques, the EEG begins to become abnormal when CBF decreases to 20 mL/100 g/min. Cellular survival is not threatened until CBF decreases to 12 mL/100 g/min. The difference in blood flow between when the EEG becomes abnormal and the blood flow at which cellular damage begins to occur provides a rational basis for monitoring the EEG during carotid surgery. In many cases, prompt detection of EEG changes may allow intervention (e.g., shunting, increasing cerebral perfusion pressure) to restore CBF before onset of permanent neurologic damage.

Serious intraoperative reduction in cerebral oxygen supply may result from surgical factors (e.g., carotid cross-clamping) that are usually beyond the anesthesiologist's control, and from factors that the anesthesiologist can correct. Reduction in CBF produced by hyperventilation, hypotension, or temporary occlusion of major blood vessels may be corrected by reducing ventilation, by restoring normal blood pressure, or, in the case of temporary vessel occlusion, by increasing blood pressure above normal. Because the EEG may readily detect cerebral ischemia, continuous EEG monitoring may be used to evaluate the effectiveness of therapy instituted to correct ischemia.

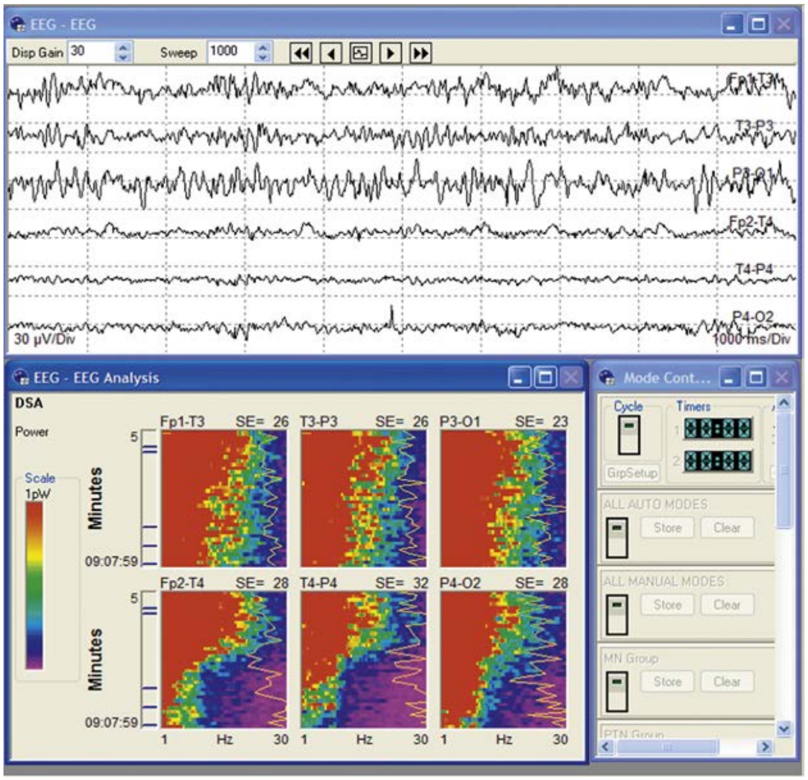
Should the patient undergoing carotid endarterectomy have EEG monitoring? That question cannot be answered based on available data. EEG monitoring provides information about CBF that would not otherwise be available. The clinician has an opportunity to intervene to increase inadequate blood flow when it occurs. Anecdotally, many clinicians have found such monitoring useful and use it routinely. Population studies do not support routine use, reflecting the fact that strokes in carotid vascular surgery are infrequent and the majority are caused by embolism, which may not be adequately treated by simply increasing CBF.

In a large series of patients undergoing carotid endarterectomy with selective shunting who were monitored with 16-channel unprocessed EEG, no patient awakened with a new neurologic deficit that was not predicted by EEG.[70] Transient, correctable EEG changes were not associated with stroke. Persistent changes were associated with stroke. This study had no comparison group, however, analyzing stroke rate when EEG monitoring was not used during surgery. Conversely, in the North American Symptomatic Carotid Endarterectomy Trial and the European Carotid Surgery Trial, retrospective comparisons of patients receiving EEG monitoring and patients not receiving EEG monitoring failed to show a significant difference in outcome.[71,72]

Even more difficult to prove is that EEG monitoring is useful when all patients are shunted during carotid clamping. Such monitoring has detected correctable shunt malfunction, and investigators have described hypotension-related EEG changes in patients with critical stenoses and poor collateral circulation.[73] Advocates of selective shunting based on EEG (or other monitoring) criteria claim that inserting a shunt unnecessarily through a region of diseased vessel would surely increase embolization. A multicenter study of 1495 carotid endarterectomies provides some evidence that shunting of patients without evidence of decreased cerebral perfusion increases the incidence of stroke more than sixfold.[74] Although this study and other more recent studies[75-77] advocate that selective shunting using some form of monitoring of the adequacy of CBF should improve perioperative stroke rate, an analysis by the Cochrane Stroke Group[78] failed to show sufficient evidence to advocate for routine shunting, selective shunting, or even no shunting at all. In addition, this review failed to demonstrate that any type of monitoring for cerebral ischemia was superior to another.

Processed EEG also has been used during carotid vascular surgery. Two issues affect the efficacy and reliability of processed EEG as a monitor for cerebral ischemia. First, what is the minimum number of channels (or areas of the brain) to be monitored? Clinical experience and clinical investigations suggest that four channels (two per side) are the minimum number of channels for adequate sensitivity and specificity.[34] When a limited number of channels were compared with 16-channel EEG monitoring, 100% sensitivity and specificity were obtained using 2 channels per hemisphere, provided that those channels monitored the middle cerebral artery territory. These results were obtained with a frontoparietal channel combined with a frontotemporal channel.[34]

The second issue is the experience level of the observer monitoring the processed EEG. Is a dedicated, experienced technician or electroencephalographer needed? In a study addressing this question, the 16-channel unprocessed EEG monitored by a dedicated technician was compared with a processed EEG reviewed by three anesthesiologists of differing levels of experience with processed EEG.[35] The three anesthesiologists interpreted the tracings without knowledge of the case. They were presented only with the written trace with an indication of the point at which the carotid artery was clamped. In these cases, the most important interpretation pitfall to avoid is the "false-negative" pattern. If the clinician interprets the EEG as showing adequate CBF when in fact it does not, the surgeon may fail to shunt



Disp Gain 30

Sweep 1000

Fig. 39.13 Hemispheric ischemia after clamping of the internal carotid artery. The top panel shows three channels of electroencephalogram *(EEG)* for each hemisphere. The right-sided channels (bottom three tracings) show nearly suppressed *EEG* activity due to ischemia. The bottom panel shows the corresponding density spectral array, where *EEG* power in each frequency is coded in color, with red indicating greater power. The oldest data is at the top of each field and the most recent at the bottom. The lower row of three density spectral array *(DSA)* panels corresponds to the right-sided *EEG* leads. Halfway through the panel there is a dramatic reduction in *EEG* power after clamp placement. The bottom spectrum corresponds to the raw *EEG* shown tracings shown in the top panel. (Image courtesy of Reza Gorji, MD.)

an ischemic patient. A false-positive result may be less of a problem because that patient is not ischemic but is given a shunt anyway. In this case, only the risk of emboli from the "unnecessary" shunt is incurred. The positive predictive value of the anesthesiologist correctly interpreting the trace as unchanged after clamping was 91% to 98%, which indicates that the device can be used by novice interpreters with fair accuracy to determine the presence of cerebral ischemia at the time of carotid occlusion (Fig. 39.13).

Somatosensory-Evoked Potentials. SSEP monitoring also has been used to gauge adequacy of CBF to the cerebral cortex and subcortical pathways during carotid vascular surgery.[49,79,80] SSEPs have been found in the laboratory to have a similar but slightly lower threshold for electrical failure compared with the EEG when CBF is reduced. SSEPs are generally intact until the cortical blood flow decreases to less than 15 mL/100 g/min.[47] A recent review (meta-analysis) of shunting during carotid vascular surgery suggests that selective shunting based on SSEP monitoring results in a perioperative stroke rate similar to when EEG monitoring is used as the basis for shunting.[81] However, logic would also suggest that changes in SSEP are unlikely, for example, with ischemia involving the anterior portions of either the frontal or temporal lobe, which could readily be detected by an appropriately placed EEG electrode. There is even less outcome evidence to support the use of SSEPs during carotid surgery than there is for the EEG, but the authors and others have found SSEPs to be useful as a simultaneous monitor with EEG to detect subcortical ischemia.[82]

Transcranial Doppler. TCD monitoring during carotid vascular surgery is based on measurement of two primary parameters—blood flow velocity in the middle cerebral artery and the number of emboli detected in the same artery. The hypothesis justifying the use of this monitoring during carotid vascular surgery has two components: blood flow velocity correlates with CBF, and increasing numbers of emboli increase the likelihood of embolic stroke. Intraoperative use of TCD has not been widely adopted for many reasons. As previously noted, good TCD signals cannot be obtained in up to 20% of individuals who could benefit from monitoring. Also, TCD probe motion during surgery causes major problems with loss of signal or with angle of insonation–induced changes in the relationship between blood flow velocity and blood flow. Nonetheless, multiple series of carotid endarterectomies with TCD monitoring have been reported with good success, quoting a critical blood flow velocity reduction around 50% as indicative of inadequate CBF requiring intervention (shunt or increased blood pressure or both).[83-89] The relationship between emboli count and stroke is better established. Multiple studies conducted in the preoperative, intraoperative, and postoperative periods indicate that higher emboli counts are associated with higher stroke risk and warrant intervention.[83-89] TCD is the only monitor able to detect dangerous hyperemia, also known as normal perfusion pressure breakthrough, after removal of a severe, flow-limiting carotid stenosis. Typically, a sustained doubling of flow velocity after unclamping should prompt the anesthesiologist to consider lowering the blood pressure. There are no good outcome data supporting TCD use intraoperatively, but data regarding emboli count and risk of stroke suggest that if technical issues with probe attachment to the patient can be overcome, TCD may be useful as a predictor of impending stroke in the preoperative, postoperative, and perhaps intraoperative periods.

Cerebral Oximetry (Near-Infrared Spectroscopy). Near-infrared spectroscopy (NIRS) is an attractive monitor during carotid endarterectomy because of its ease of application and lack of training required for interpretation. The hypothesis governing its use is very simple: as oxygen delivery to the brain decreases, oxygen extraction from arterial blood increases, and the oxygen saturation in cerebral venous blood decreases. Multiple case reports and series document the use of cerebral oximetry during neurovascular surgery, but several major questions surrounding use of NIRS during carotid surgery remain unanswered.

The first and most important question is what degree of decrease in oxygen saturation can be tolerated before intervention is necessary. Because most interventions involve some risk (e.g., shunt → emboli, increased BP → myocardial ischemia), the answer to this question is important. The answer does not yet exist, however, and may vary from patient to patient. Two studies in awake patients showed that the saturation value at which any patient would develop symptoms varied from patient to patient,[12,13] and an absolute value that required shunting could not be determined. Another study showed that cerebral oxygen saturation decreased before the EEG developed changes, and the authors used this observation to claim superiority for NIRS monitoring of the brain during carotid surgery.[90] This finding should not be surprising, however, because function of the brain (in this case, electric function) does not fail until increased extraction of oxygen no longer meets metabolic demands for the tissue. If metabolic demands are being met by increased extraction, it is unclear that intervention is needed.

Finally, a study by Friedell and colleagues[91] compared NIRS with EEG and SSEP monitoring during carotid surgery. In 24 of 323 patients, significant differences were observed between NIRS and monitors of electric function. Seventeen patients showed no changes in electric function with significant decreases in cerebral oxygen saturation. In seven patients, no change in cerebral oxygen saturation occurred despite significant change in the EEG and SSEP. The latter finding may be due to the fact that NIRS and EEG/SSEP monitor different vascular territories. These data in combination with the data from studies in awake patients suggest that use of NIRS alone during carotid vascular surgery may be inappropriate. In addition, an aggregate of studies and case reports available in the literature suggests that there is no clear cutoff value of regional oxygen saturation which would mandate shunt placement or increasing the cerebral perfusion pressure.

Intracranial Neurovascular Surgery (Monitors: Somatosensory-Evoked Potentials, Motor-Evoked Potentials)

Somatosensory-Evoked Potentials. SSEPs have been extensively studied during cerebral aneurysm surgery. During these procedures, the surgical incision and brain retraction diminishes the utility of placing EEG scalp or brain surface electrodes that could detect cerebral ischemia in at-risk cortex. Recording electrodes placed on the surface of the brain have been used successfully, but they are commonly considered “in the way” by neurosurgeons. Thus EEG is typically used only to confirm metabolic suppression during temporary clip placement. Scalp electrodes for SSEP monitoring may be placed more easily, although the recording montage is frequently not the same as that used in an awake patient.

For aneurysms involving the anterior cerebral circulation, SSEP monitoring has an excellent, but not perfect, record for predicting postoperative neurologic function. Most patients without surgically induced SSEP changes during the procedure awaken with an unchanged neurologic examination. Patients with significant SSEP changes that do not revert to normal awaken with a new neurologic deficit. Patients with significant intraoperative SSEP changes that return to normal may show at least a transient postoperative deficit, with the severity and duration of that deficit increasing as the severity of the SSEP change increases. Many authors have reported significant utility of SSEP monitoring in detecting improper aneurysm clip placement (see Fig. 39.12) and in guiding intraoperative blood pressure management, particularly in patients already showing, or at significant risk for, vasospasm after subarachnoid hemorrhage.[48,92-97] The same success cannot be reported, however, for posterior circulation aneurysms. In these cases, many areas of the cortex and subcortical structures are at risk for damage that cannot be monitored at all by somatosensory pathway function. A significant false-negative monitoring pattern exists for these patients, but changes can still be detected when a surgical insult is sufficiently severe to involve large portions of the brain.[98-101]

An important concern during aneurysm surgery is injury to perforating vessels near the aneurysm, which risks damage to subcortical pathways in the internal capsule and may account for half the new neurologic deficits immediately postoperatively.[102] Anatomically, the motor pathway runs anterior to the sensory pathway in the internal capsule and is at greater risk if the anterior choroidal artery, lenticulostriate perforator vessels, or even perforating branches of the anterior cerebral artery are injured during dissection and clip placement. Two concerns need to be addressed if tcMEP is to be incorporated successfully in these cases. First, motion caused by stimulation needs to be minimized to not interfere with the surgery. Second and more importantly, stimulus parameters need to be set to limit deep current spread that would activate the corticospinal tract distal to the internal capsule and obscure ischemia of the proximal pathway. The use of longer stimulus trains at intensities close to the motor threshold addresses both concerns[103] and have made tcMEP monitoring a useful adjunct during aneurysm surgery in many centers.[104]

SUPRATENTORIAL INTRACRANIAL NONVASCULAR SURGERY (MONITORS: AWAKE PATIENT, ELECTROENCEPHALOGRAM, SOMATOSENSORY-EVOKED POTENTIALS)

The most comprehensive approach to the problem of functional localization of brain structures that need to be preserved to achieve a good outcome is to perform entire segments of a supratentorial craniotomy in an awake patient, who is undergoing repeated neurologic examinations targeted to assess the eloquent area at risk. Such procedures are typically divided into exposure, mapping, and resection phases, and can be done with the patient entirely awake or awake only during periods when the neurologic examination needs to be assessed.[105] Common to all these approaches is the need for meticulous locoregional anesthesia of the scalp at the craniotomy site and the pin sites of the head holder. A second requirement is a patient who is well informed about the awake parts of the procedure and willing and able to cooperate. Dexmedetomidine, propofol, and remifentanil are the agents most frequently incorporated into the anesthetic regimens for awake craniotomy.[106] Complications of awake craniotomy include nausea and vomiting, respiratory problems, and "tight" brain, but are typically mild and occur in less than 10% of cases in experienced centers. Seizures triggered by cortical stimulation can be stopped by the application of iced saline to the exposed cortex or a small amount of barbiturate or propofol.

Seizure Focus Localization Surgery

Patients with epilepsy who have seizures that generalize from an anatomically distinct focus may benefit greatly from the surgical resection of that seizure focus.[107] Precise localization of a seizure focus is important for achieving the therapeutic objective of seizure control and for minimizing complications from the resection. With sensitive magnetic resonance tomography techniques, neuronavigation, and recordings of typical seizure activity in the awake patient after placement of subdural and depth electrodes, the anatomic location and the appropriate extent of the resection frequently can be determined preoperatively.[108] These developments have diminished the role of intraoperative recordings from the epileptogenic zone using electrocorticography.

Electrocorticography is done by placing a grid of subdural electrodes onto the exposed brain surface and recording spontaneous electric activity. Electrocorticography is constrained by several limitations. The time for such recordings is limited to a few minutes; recordings are limited to interictal discharges, which may not correlate with the epileptogenic focus; and recordings need to be obtained from a brain that is under the effects of general anesthetic agents, which alter the EEG.

To provide good conditions during the recording, the level of anesthesia is lightened (e.g., by use of a strict nitrous oxide–narcotic technique or low concentrations of volatile anesthetic drugs). Provocative techniques, such as hyperventilation or administration of a small dose of methohexital, may be useful to activate the seizure focus. Intraoperative seizure mapping requires the involvement of an expert electroencephalographer familiar with this technique.

Motor Strip Localization

Electrophysiologic monitoring of the somatosensory system in anesthetized patients can provide a simple anatomic guide to the location of the rolandic fissure, which separates the parietal primary sensory and frontal primary motor cortex. The fissure is located by recording cortical SSEPs from a subdural strip electrode that is placed perpendicular to the presumed location of the fissure. The exact location of the fissure is characterized by a reversal in the polarity of the primary cortical response between the electrodes straddling the fissure, as illustrated in the clinical example in Fig. 39.14. Subsequent placement of the electrode strip onto the primary motor area of the precentral gyrus allows subsequent monitoring of the corticospinal tract through direct cortical stimulation.

POSTERIOR FOSSA SURGERY (MONITORS: BRAINSTEM AUDITORY-EVOKED POTENTIALS, CRANIAL NERVE MONITORING, SOMATOSENORY-EVOKED POTENTIALS, MOTOR-EVOKED POTENTIALS)

Besides the cerebellum, the posterior fossa contains within the narrow space of the brainstem many crucial neural structures, including the following: the ascending and descending sensorimotor pathways; cranial nerve nuclei; cardiorespiratory centers; the reticular activating system; and the neural networks that underlie crucial protective reflexes, such as eye blink, swallowing, gag, and cough. Posterior fossa surgery is not undertaken lightly, and even small injuries can leave significant neurologic deficits. Although some of these neural structures, such as the sensory, voluntary motor, or auditory pathway, can be monitored consistently, intraoperative integrity of other neural structures is frequently only inferred from the well-being of neighboring structures amenable to monitoring.

Microvascular Decompression of Cranial Nerves V, VII, and IX

Microvascular decompression is done most frequently for trigeminal neuralgia (cranial nerve V) in patients who present acceptable medical risks for a posterior fossa craniotomy. More rarely, the same approach is used to treat hemifacial spasm or neurovascular compromise of lower cranial nerves. The surgery entails dissecting along the intracranial portion of the nerve, identifying offending blood vessels that encroach on the nerve, and placing an insulating Teflon pad between vessel and nerve. The surgery risks ischemic damage to perforating vessels arising from the offending arteries and cerebellar retraction–related damage to cranial nerves. The facial and vestibulocochlear nerves are at particular risk for stretch-induced injury caused by medial retraction of the cerebellum. Retraction-induced stretch produces a prolongation of the interpeak latency between peaks I and V of the BAEP waveform, ultimately leading to a complete loss of all waves beyond wave I (Fig. 39.15). Failure to release retraction in a timely manner results in postoperative hearing loss. Such monitoring increases the chances for preserved hearing after microvascular decompression.[109-113] During microvascular decompression of the facial nerve for hemifacial spasm, recent developments using EMG monitoring

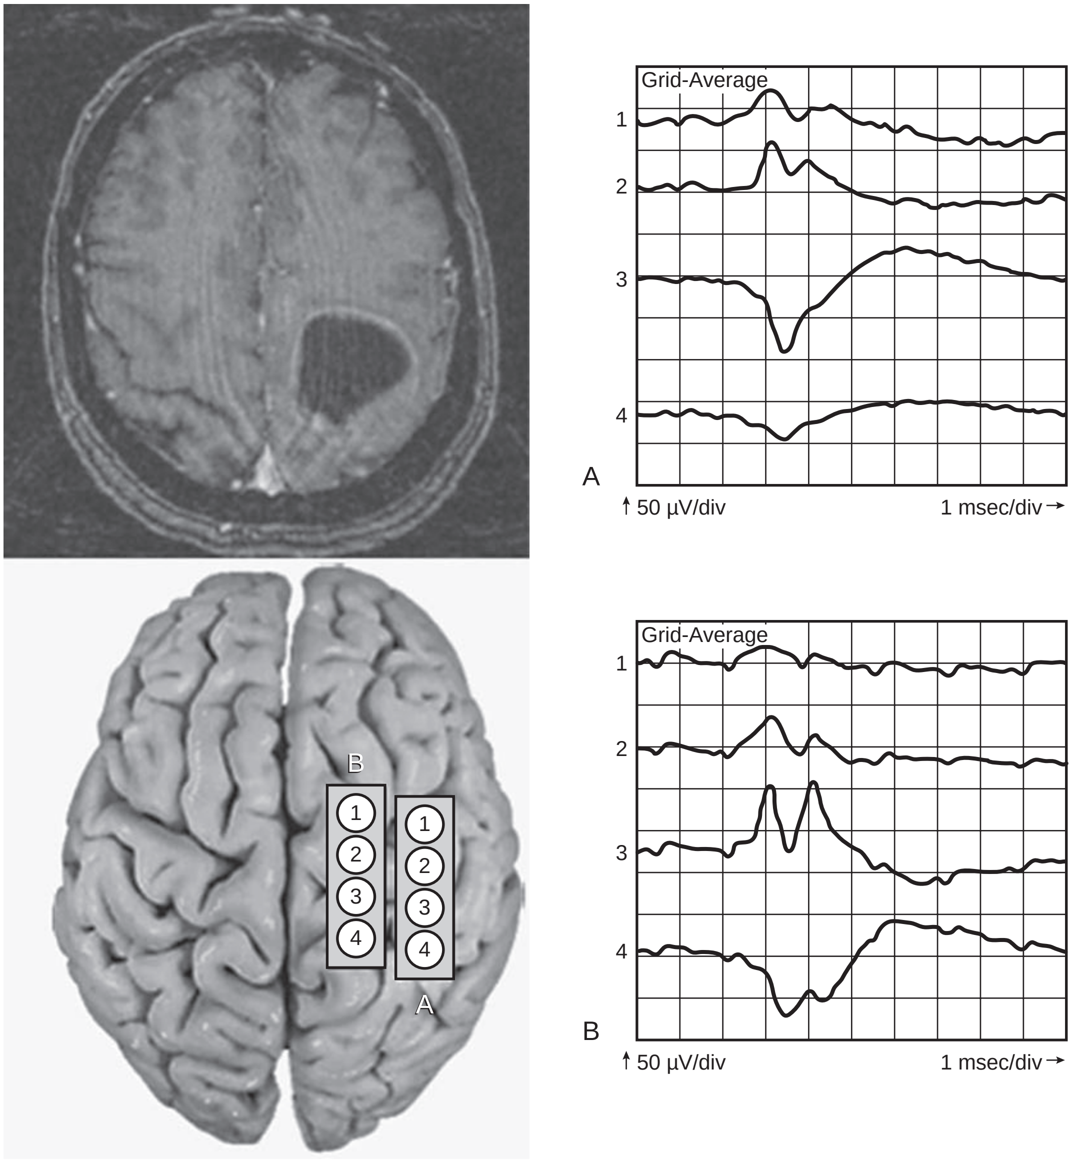


Fig. 39.14 Intraoperative localization of the rolandic fissure separating the primary sensory and motor cortex. The clinical example is from a patient with a large parietal tumor shown in the scan. Two of the recordings made from a four-contact subdural electrode strip are shown. The relative positions of the strip electrode are labeled B and A. In recording A, the primary cortical response from the electrodes anterior to the rolandic fissure shows an upward deflection, whereas the response from electrodes posterior to the fissure shows a downward deflection. Moving the strip electrode anteriorly (recording B) moves this “phase reversal” between electrodes 3 and 4.

have enabled better documentation of the adequacy of nerve decompression and lessen the likelihood of persistence or recurrence of hemifacial spasm postoperatively. This new technique monitors the so-called lateral spread response (LSR) of the facial nerve. A peripheral branch of the facial nerve is stimulated. In the normal patient, this stimulation would not result in a recordable EMG response in a muscle innervated by a different branch of the facial nerve. In patients with hemifacial spasm, EMG responses can be recorded in muscles innervated by a different branch of the facial nerve (an LSR) indicating abnormal crossover of electrical activity. Decompression of the facial nerve has been shown in multiple studies to result in a great decrease or elimination of this LSR, and studies have indicated that elimination of the LSR is highly predictive of immediate postoperative relief of hemifacial spasm.[114]

Vestibular Nerve Schwannoma

Vestibular nerve schwannomas are the most common tumors located in the cerebellopontine angle. Because of the common origin of the cochlear component of cranial nerve VIII and the essentially identical intracranial trajectory of the facial nerve, hearing loss and facial nerve palsy are concerns during surgical resection of these tumors. Size and preoperative auditory function are the best predictors of postoperative hearing.[115] For tumors up to about 1.5 cm in diameter, monitoring of BAEPs can increase the chances of preserving hearing.[116] In addition to BAEPs, the facial nerve is monitored through spontaneous and stimulated EMG. Prospective trials have shown a higher percentage of patients with a functional facial nerve 1 year after surgery if facial nerve monitoring was used. Tonic discharges warn of impending damage caused by stretch or heat

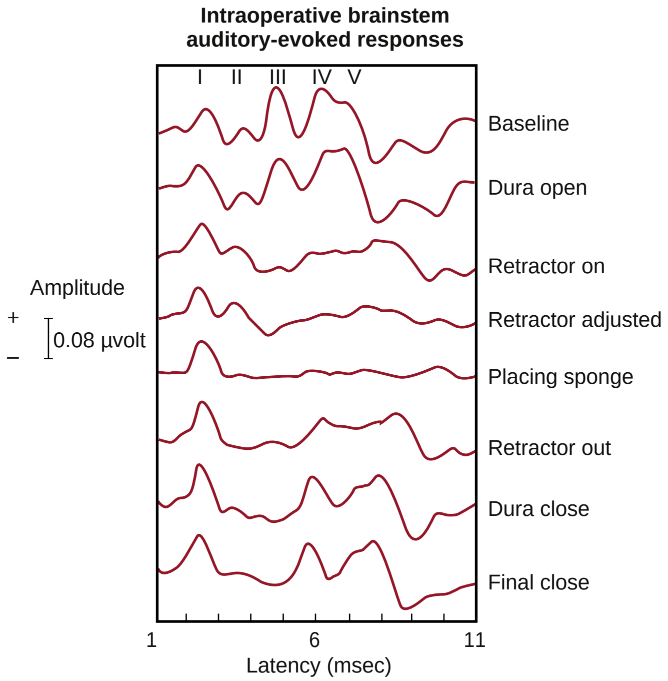

Fig. 39.15 Intraoperative monitoring of brainstem auditory-evoked responses during microvascular decompression. The baseline recording shows the typical five waves of the brainstem auditory-evoked potential response. Intraoperative events are designated to the right of each trace. Placement of the retractor causes a severe increase in latency of wave V even after adjustment of retraction. During placement of the sponge, all waves subsequent to wave I, which originates in the inner ear, are nearly completely lost. Removal of the retractor causes brainstem auditory-evoked potentials to revert toward baseline.

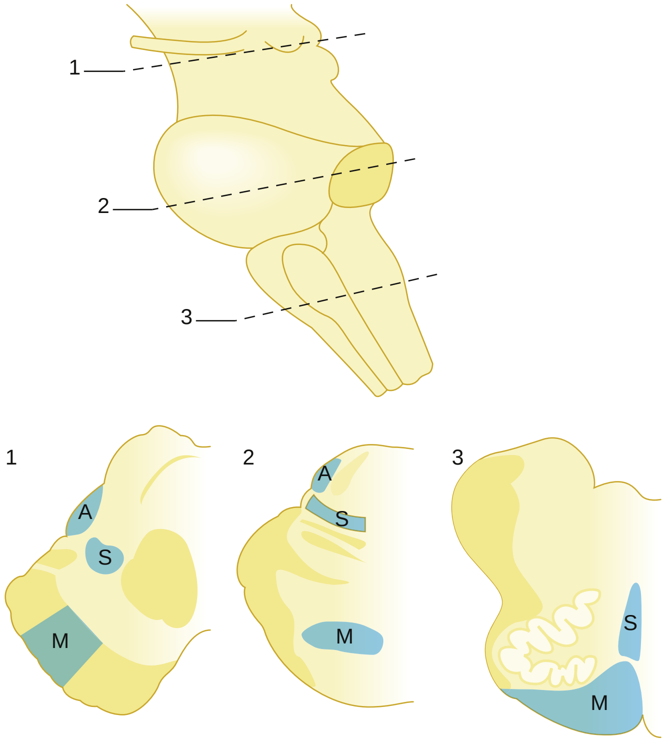

Fig. 39.16 Monitoring of the brainstem with evoked potentials. Evoked potentials monitor specific tracts that encompass defined areas in the brainstem. This is shown in three transverse sections approximately at the levels indicated in the drawings. The areas directly monitored by a given modality are indicated in blue and labeled *M* (motor), *S* (somatosensory), and *A* (auditory). Conclusions about the well-being of the remainder of the brainstem are made by inference from the monitored areas.

(e.g., electrocautery). Sharp section of the nerve may elicit no discharge, and neuromuscular blockade may eliminate the ability to monitor. If the course of the nerve is displaced by the tumor, the surgeon can map its course with a handheld stimulator and real-time auditory feedback.

Other Posterior Fossa Neoplasms

Monitoring for operations on other neoplasms located in the brainstem typically is individualized to each particular case or to the particular surgical approach. EMG and compound muscle action potentials may be recorded not only from the territory of the facial nerve, but also from the tongue to monitor the hypoglossal nerve, and from the glottis through electrodes embedded into a specialized endotracheal tube to monitor the vagus nerve. Such a setup can be used to map the floor of the fourth ventricle functionally, if it is distorted by a tumor.[117] Such monitoring may be insufficient to preserve vital reflexes because only the efferent limb of these reflexes is monitored by recording EMG from innervated muscle. MEPs can be recorded from orbicular oris, or mentalis, to assess the integrity of the facial nerve motor nucleus as well as the proximal facial nerve when tumors prevent visualization of the proximal portion of cranial nerve VII. MEPs can also be recorded from tongue as well. Obtaining these responses relies on placement of additional stimulating electrodes and optimization of stimulating conditions.

Use of neurologic monitoring for brainstem ischemia, although done in some centers, is not well documented or supported by clinical studies. Global well-being of the brainstem may be monitored by combining multiple modalities of evoked potentials, such as BAEPs, SSEPs, and MEPs. Each modality monitors a function whose integrity would be considered important in its own right for the functional outcome of an individual patient. As illustrated in Fig. 39.16, the cross-section monitored by combining all these modalities still leaves out crucial areas. Given that perfusion occurs through perforating vessels, it is easy to see that monitoring may indicate that all is well or, more likely, that a therapeutic intervention was helpful in restoring function, when clinically the patient is still left with a significant deficit. This occurrence invalidates neither monitoring nor the therapeutic intervention, but indicates only that the monitored pathway was not located in an area at risk from the surgical procedure. Because of such obligatory "false-negative" results, few studies address the utility of such monitoring. Given that each individual monitoring modality comes with its own constraints, such an approach typically requires a dedicated neurophysiologist for interpretation and troubleshooting.

SPINAL COLUMN AND SPINAL CORD SURGERY (MONITORS: SOMATOSENSORY-EVOKED POTENTIALS, MOTOR-EVOKED POTENTIALS, ELECTROMYOGRAM, AND BULBOCAVERNOSUS REFLEX)

Intraoperative monitoring of SSEPs has been used most extensively in patients undergoing surgical procedures involving the spinal column or spinal cord, or both. Extensive experience has been gained in patients who have decompressive laminectomies or who have undergone corrective procedures for scoliosis. Intraoperative changes in SSEPs have been noted in 2.5% to 65% of patients undergoing surgical procedures on the spine or spinal cord.[118-121] When these changes are promptly reversed either spontaneously or with interventions by the surgeon or anesthesiologist (e.g., lessening the degree of spine straightening in scoliosis surgery or increasing arterial blood pressure), the patients most often have preserved neurologic function postoperatively. When these changes persisted, however, the patients most often awakened with worsened neurologic function.

False-negative (rare) and false-positive (common) results have been reported with SSEP monitoring during spine surgery. Patients with intact SSEPs throughout the procedure have awakened with a new significant neurologic deficit, but the total reported incidence of this finding is far less than 1% of all cases monitored. Patients with no postoperative neurologic deficit commonly experience significant changes in intraoperative SSEPs.[70] This monitoring pattern is most commonly caused by failure to control for other, nonpathologic factors that may alter the SSEP. Overall, the reliability of properly performed SSEP monitoring to predict the postoperative sensory and motor function has been reported to be excellent.[41,121,122] Motor tracts are not directly monitored by SSEPs, however. In addition, the blood supply to the dorsal columns of the spinal cord, which carries all of the upper extremity SSEPs and at least a portion of the lower extremity SSEPs, is derived primarily from the posterior spinal arteries. The blood supply to motor tracts and neurons is derived primarily from the anterior spinal artery. It is possible for a significant motor deficit to develop postoperatively in patients with intact SSEPs throughout the operative course. Such events have been reported.[123,124]

In operations on the spinal column and after acute spinal cord injury, the sensory and motor changes generally correlate well;[41] however, in patients with neurologic dysfunction after thoracic aortic vascular surgery, frequently posterior spinal cord function (proprioception, vibration, light touch) is left intact when motor and other sensory functions (pain, temperature) are impaired. This result occurred in 32% of patients with neurologic injury after aortic aneurysm repair in one series,[125] with similar results in many other series. Intraoperative SSEP monitoring in these patients carries a significant risk for false-negative results, and as a result, such monitoring is not widely used.

Multiple anecdotal reports and an increasing number of case series suggest that MEP monitoring during surgery on the spine or its blood supply is useful. Several series have reported significant changes in MEPs without changes in SSEPs. These series suggest that combined use of SSEP monitoring and MEP monitoring may eliminate false-negative monitoring patterns during spine surgery.[126-131] In a consensus statement, the American Society of Neurophysiologic Monitoring concluded that use of MEP monitoring in combination with SSEP monitoring is well established to prevent injury to sensory and motor tracts during spinal column surgery.[132] In the case of monitoring paraplegia risk during thoracoabdominal aneurysm surgery, the literature shows mixed but improving support for the use of MEP monitoring. Two earlier studies suggested that MEPs may not be as effective as hoped. The first study recorded MEPs from the lumbar spinal cord in dogs produced by transcranial electric stimulation.[133] Elmore and associates found that these spinally recorded potentials did not accurately predict postoperative motor function. In a second study, Reuter and colleagues[134] recorded MEPs at the spinal cord and the peripheral nerve level in dogs produced by transcranial electric stimulation. They also found that the spinally recorded responses were inaccurate in predicting motor function postoperatively. The peripheral nerve responses disappeared in all animals and were not present 24 hours later regardless of whether the animal could move its lower extremities.

These studies suggest that the spinally recorded MEP likely represents a response generated by the descending corticospinal tract. This white matter pathway is resistant to ischemia compared with the more metabolically active anterior horn cells (gray matter). Recovery of this white matter–generated MEP response could occur after reperfusion of the cord, whereas the gray matter might not recover. Responses recorded from the peripheral nerve would reflect postsynaptic anterior horn cell function, but lower extremity ischemia occurring after aortic cross-clamping may preclude recording this or the response from muscles during surgery.

More recent clinical series have shown much greater success with MEP monitoring during aortic vascular surgery in correctly detecting inadequate spinal cord blood flow and in improving operative outcome. The technique has proven useful, particularly when operative strategies such as reimplantation of crucial intercostal vessels based on results of MEP monitoring, alteration of spinal cord perfusion pressure (blood pressure increase or cerebrospinal fluid drainage or both), spinal cord cooling, and other methods are used.[135] Additional studies, particularly with the use of endovascular stent repair of thoracoabdominal aneurysms, have found MEPs very useful in guiding therapy and improving outcome.[136,137]

For surgeries involving the conus medullaris and sacral nerve roots such as untethering of the spinal cord or resection of a lipoma of the filum terminale, tcMEPs can be recorded from the anal sphincter. In addition, the reflex arc of the bulbocavernosus reflex can be recorded, by stimulating the pudendal nerve and recording a motor response from the anal sphincter.[138]

PERIPHERAL NERVE SURGERY (MONITORS: ELECTROMYOGRAM, NERVE ACTION POTENTIAL)

Neurologic monitoring for surgeries involving peripheral nerves can be done in two different settings. In the first setting, the peripheral nerve is intact, but threatened by the surgery. Examples would be an intrinsic nerve tumor, such as a schwannoma or an extensive soft tissue tumor, particularly if it displaces the normal anatomic course of a nerve. Monitoring of spontaneous and stimulated muscle responses from muscle groups innervated by the nerve in question can be used to guide the resection. Spontaneous EMG discharges can be generated by stretch or compression of the nerve, by local heating from electrocautery, or from ischemia. Two caveats apply to the monitoring

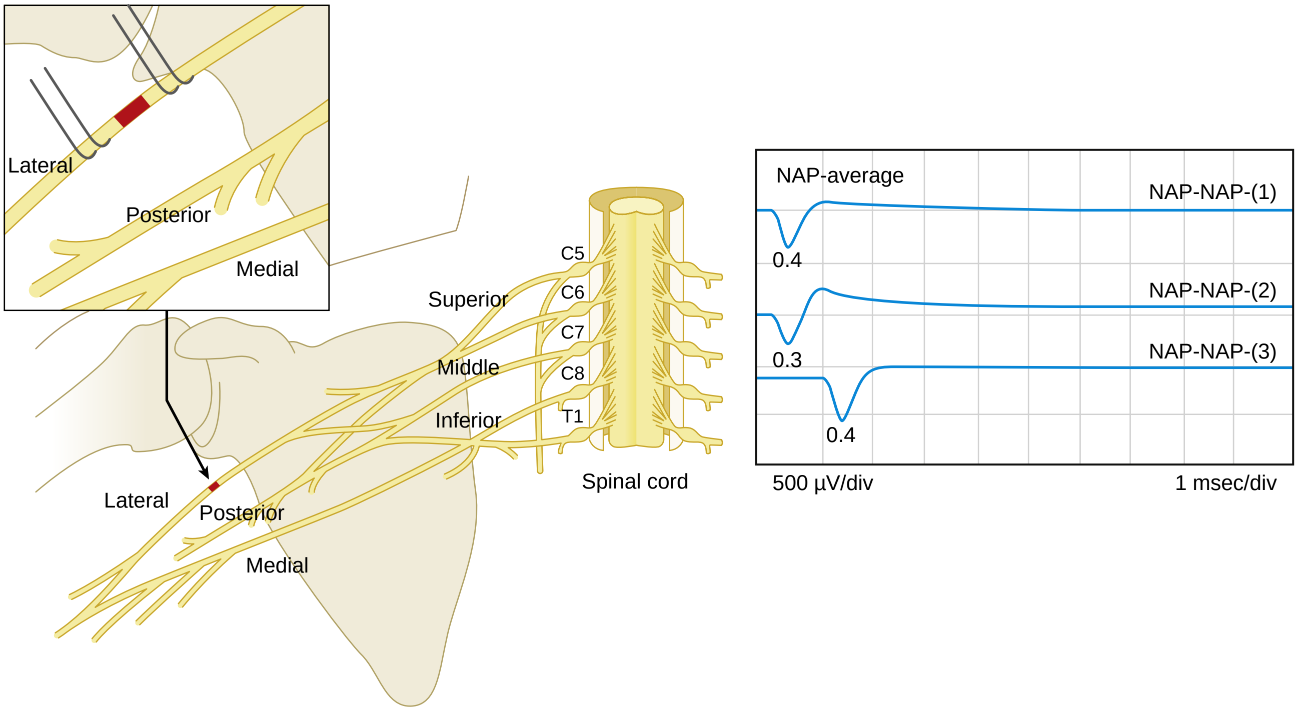

Fig. 39.17 Recording a nerve action potential *(NAP)* during a brachial plexus exploration. The site of the injury on the lateral fascicle is indicated in red. As shown in the inset, the surgeon places hook electrodes on either side of the exposed part of the nerve. If the injury is limited to an axonotmesis, proximal stimulation will result in a distal NAP similar to the ones shown in the recording to the right. The delay in the response in the third tracing is simply the result of a change in technical settings.

of spontaneous EMG. First, the neuromuscular junction is part of the monitored pathway, and muscle relaxation decreases/abolishes the sensitivity of monitoring in a dose-dependent manner. Second, sharp section of the nerve may not result in a noticeable discharge. To search out the course of the nerve intraoperatively, the surgeon may stimulate the wound area with a hand-held probe and listen for stimulated EMG or palpate for muscle contraction. The underlying concept should be familiar to anesthesiologists from the use of nerve stimulators in regional anesthesia.

A variation of this technique of monitoring that is in widespread use, because it is conceptually simple, is monitoring of pedicle screw placement during spinal instrumentation with the aim of avoiding nerve root injuries owing to malpositioned pedicle screws.[139,140] The aim is to avoid malpositioned screws that weaken the construct or cause postoperative radicular pain. Typically, the pilot hole or, less desirable, the shank of an implanted pedicle screw is stimulated repetitively with increasing current to determine the threshold for eliciting a dermatomal compound muscle potential. The interpretation of responses is complicated by the fact that the anatomical relationship between pedicles and nerve roots depends on the level of the spinal cord because the spinal cord is shorter than the bony spinal column. Thus a medially misplaced screw in the lumbar region will come to lie next to a nerve root, whereas in the thoracic spine, a medial misplacement puts the screw next to the corticospinal tract, which cannot be activated by single stimuli. Because thresholds vary among cervical, thoracic, and lumbar spine, as well as between healthy and diseased nerve roots, this technique has limitations but is widely thought to be useful.[141]

A second setting where monitoring of peripheral nerves is used is in patients with prolonged weakness and sensory loss after nerve injury undergoing nerve exploration.[142] The aim is to determine whether nerve reconstruction may improve outcome. The area of the lesion is determined by preoperative nerve conduction studies. Intraoperatively, the nerve is first stimulated proximal to the lesion, and a recording of the nerve action potential is made directly from the nerve distal to the lesion, as illustrated in Fig. 39.17. If there is nerve conduction across the lesion, lysis of scar is performed, and the incision is closed. Natural recovery by means of axonal regrowth produces the best outcome. If conduction does not occur across the lesion, resection of the damaged nerve and nerve cable grafting is performed.[65,143,144]

APPLICATIONS OF INTRAOPERATIVE MONITORING TO PEDIATRIC PATIENTS

In recent years many of the techniques described above have been used during surgery on children as young as 6 weeks of age. Very young children present special challenges due to the immaturity of the CNS. Incomplete myelination of specific tracts that carry sensory or motor signals is the primary source of the challenges. While light anesthesia (0.5 minimum alveolar concentration [MAC] volatile anesthetic) allows MEPs to be elicited from healthy adolescents, infants and young children are exquisitely sensitive to the effects of volatile anesthetic drugs. Therefore total intravenous anesthesia (TIVA) techniques are the anesthetics of choice when recording evoked potentials from these patients. In addition, adaptive strategies need to be applied by the monitoring team to overcome the effects of myelination delays and other developmental factors (Table 39.2).

TABLE 39.2 Additional Considerations When Monitoring Infants and Young Children

Modality	Observation	Developmental Neurophysiology	Compensation Strategy
SSEPs—MN & UN	Prolonged Erb's to cortical or cervical to cortical inter-peak latency	Incomplete myelination of medial lemniscus and thalamocortical pathways	Avoid volatile anesthetic drugs, avoid burst suppression, reduce stimulation rate
SSEP—PTN	Difficult to obtain; low amplitude	Incomplete myelination of dorsal columns; asynchronous volleys	As above, increase pulse length; optimize signal:noise ratio
tcMEP		Cortical and spinal cord motor neurons very susceptible to effects of volatile agents. Variance in conduction velocity of large CST fibers exceeds mean conduction velocity	TIVA, may need low-dose ketamine to help support BP. Double-train stimulation with unequal train lengths; optimizing inter-train interval
D-wave	Difficult to obtain in children under 24 months of age	Signal dispersion due to large variance in conduction velocities	Electrodes with larger surface area may be helpful
ABR	Low quality signals with volatile agents	uncertain	TIVA for ABR for less than 24 months
Bulbocavernosus Reflex	Very susceptible to effects of volatile agents	Oligosynaptic reflex; sensitivity to volatile agents persists	Double pulse train with large inter-train interval

ABR, Auditory brainstem response; *D-wave,* positive or negative deflection recorded from electrodes placed directly over the spinal cord; *SSEPs,* somatosensory-evoked potentials; *tcMEP,* transcranial motor-evoked potential; *TIVA,* total intravenous anesthesia.

Modified from Francis L, Busso V, McAuliffe JJ. Intraoperative neuromonitoring in pediatric surgery. In: Koth A, Sloan TB, Toleikis JR, eds. *Monitoring the Nervous System for Anesthesiologists and Other Health Care Professionals*. Cham: Springer Int; 2017.

Some monitored surgical procedures are performed almost exclusively in children. One example is selective dorsal rhizotomies for relief of spasticity associated with cerebral palsy. This procedure involves interrogation of lower extremity dorsal root subdivisions (rootlets) and evaluating the compound action potentials generated in response. This technique is best performed with a TIVA technique. Infant/toddler hearing evaluations may require the use of auditory brainstem response tests under anesthesia. Experience at the Cincinnati Children's Hospital Medical Center (CCHMC) suggests that a propofol infusion anesthetic yields a more reliable assessment of wave V than a sevoflurane-based anesthetic.

It is important to recognize that the EEG patterns associated with an anesthetic state in adults do not apply to infants under anesthesia. Infants less than 3 months have almost no change in their EEGs when transitioning from a quiet resting state to an anesthetized state as slow wave patterns dominate both states. Alpha and theta patterns emerge under anesthesia at 4 months of age but differ from those of older children and adults.[145]

In summary, infants and young children can benefit from intraoperative neurophysiological monitoring if both monitoring and anesthetic techniques are appropriately modified.

NONNEUROLOGIC SURGERY THAT RISKS DAMAGE TO THE CENTRAL NERVOUS SYSTEM (MONITORS: ELECTROENCEPHALOGRAM, TRANSCRANIAL DOPPLER, CEREBRAL OXIMETRY, JUGULAR VENOUS OXYGEN SATURATION)

Cardiopulmonary Bypass

Electroencephalogram. In humans, changes that occur with the institution of CPB may alter the EEG by multiple different mechanisms. Plasma and brain concentrations of anesthetic drugs may be altered by CPB or by anesthetic drugs commonly given during CPB, alterations in arterial carbon dioxide tension and arterial blood pressure may occur, and hemodilution with hypothermic perfusate nearly always occurs. These effects, all of which may produce EEG changes similar to pathologic changes seen with ischemia, make it difficult to interpret EEG changes occurring during CPB.

Levy and others[146,147] tried to distinguish the normal effects of hypothermia from other events occurring at the institution and conclusion of CPB. Initially, Levy concluded that only a qualitative relationship could be determined, but later, with the use of a much more sophisticated EEG analysis technique (approximate entropy), EEG changes associated with changes in temperature could be quantified.

Chabot and colleagues[148] and Edmonds and colleagues[149] have attempted to use quantitative (processed, multiple-channel) EEG during CPB to detect cerebral hypoperfusion and relate these changes to postoperative neurologic function. In addition, some minimal work has been done with intervention after detection of cerebral hypoperfusion using quantitative EEG. Although the data seem promising, only a few patients have been studied, with very few corroborating studies. In addition, this type of monitoring is extremely costly in time, personnel, and equipment. Given the lack of convincing outcome data, the cost-to-benefit ratio is unclear at best. Some other investigators failed to show any convincing relationship between intraoperative EEG parameters and postoperative neurologic function, especially in small infants and children.[150,151] Whether the processed, quantitative EEG provides useful information for clinical management of patients during CPB is not clear. None of the currently available studies and recommendations would support an evidence-based justification for their routine application. However, use of EEG to document electrocortical silence and maximum reduction of cerebral metabolism prior to institution of circulatory arrest seems logical.

Transcranial Doppler. TCD ultrasound can monitor the cerebral circulation during CPB. Anecdotal reports and case series document the use of TCD for determining adequacy of CBF, detection of emboli, and detection of improper cannula placement.[152] Only very limited outcome data exist, and use of TCD ultrasound during CPB does not stand up to evidence-based examination, primarily because of lack of information. Probe placement instability and inability to obtain signals in some patients also have limited the use of this monitor intraoperatively. Finally, although the hypothesis that cerebral microemboli are at least part of the pathogenesis of postoperative cognitive decline following CPB is attractive, a recent study failed to demonstrate any relationship between CPB counts of presumed emboli and postoperative cognitive dysfunction.[153]

Cerebral Oximetry and Jugular Venous Oxygen Saturation. As is the case with EEG monitoring during CPB, there are multiple case reports and several series that advocate the use of NIRS or jugular venous oxygen saturation ($Sjvo_2$) as indicators of adequate perfusion of the brain during CPB.[154,155] Incorrect placement of CPB cannulae has been detected clinically and in laboratory studies. One more recent series of patients undergoing CPB for coronary bypass surgery showed a higher incidence of major organ system dysfunction and longer hospital stays in patients with lower baseline and intraoperative cerebral oxygen saturation values.[156] The same questions exist for this application of NIRS, however, as do for the use of NIRS during carotid vascular surgical procedures. Although a recent systematic review of the use of NIRS during CPB showed that data are insufficient to conclude that interventions based on low cerebral oxygen saturation values prevent either stroke or postoperative cognitive dysfunction,[157] several more recent studies suggest significant promise for this modality when used in combination with TCD ultrasound. Use of NIRS and TCD ultrasound together identified a significant percentage of patients undergoing CPB with impaired autoregulation who were at higher risk for postoperative cognitive dysfunction and/or stroke.[158-160] This patient population may benefit from higher mean arterial pressure (MAP) during CPB. Use of NIRS during CPB clearly provides information that would not otherwise be available, but more work is needed before we fully understand the role of this monitor during CPB.

$Sjvo_2$ is very invasive. Although data from case reports and studies suggest that $Sjvo_2$ may have utility in detecting inadequate CBF, lack of outcome data, lack of clearly defined critical values at different temperatures during CPB, and availability of less invasive modalities (EEG, cerebral oximetry) have resulted in only limited use of this monitoring method during CPB. Based on current information, no neurologic monitoring techniques, either alone or in combination, are clearly useful in improving outcome during surgical procedures requiring CPB. Further research is needed before the cost in personnel and equipment of neurologic monitoring during CPB can be justified.

INTENSIVE CARE APPLICATIONS OF NEUROLOGIC MONITORING (MONITORS: ELECTROENCEPHALOGRAM, EVOKED POTENTIALS, TRANSCRANIAL DOPPLER, JUGULAR VENOUS OXYGEN SATURATION)

Secondary injury to the CNS has been recognized in past decades as a major modifiable risk factor in patients with CNS disease. Aneurysmal subarachnoid hemorrhage, stroke, and traumatic brain injury are examples of CNS insults in which secondary injury has important implications for the ultimate functional outcome.[161-163] These same diseases frequently result in a primary insult to the CNS that severely constrains the utility of the clinical neurologic examination because of the need for mechanical ventilation and sedation. Many techniques of neurologic monitoring discussed earlier are used in the intensive care unit. Generally, however, techniques that require the continued presence of skilled technologists, such as monitoring of evoked potentials, are prohibitively expensive and of less practical value than techniques that provide data that easily integrates into the physiologic support provided through intensive care or techniques that can be performed as daily assessments. Some of this neurophysiologic data can provide important prognostic information in comatose patients and guide decision making.

Continuous Electroencephalogram Monitoring

Continuous EEG monitoring may be of benefit in comatose patients. It facilitates timely intervention for specific diagnoses, such as nonconvulsive seizures, as the underlying cause of a fluctuating neurologic status, or point to focal problems such as regional ischemia due to vasospasm after subarachnoid hemorrhage.[164] The perceived utility of continuous EEG monitoring has led to a degree of standardization in indications and the logistics of the application of this technique in the intensive care unit.[165,166]

Cerebral Ischemia

Cerebral ischemia is an important cause of secondary injury to the CNS. It can be difficult to detect in patients who are either comatose or sedated, but can occur even in patients with adequate cerebral perfusion pressure.[167,168] Three techniques may provide intensivists with additional information about cerebral perfusion. None of the monitors is considered “standard of care.” As with all monitors, the impact of the monitor on outcome depends on the quality of the therapeutic interventions that result from integration of the additional data into the clinical management of a given patient.

$Sjvo_2$ monitoring is used most extensively in the intensive care unit to monitor patients with traumatic brain injury. The data have been used to guide blood pressure and ventilatory management to optimize blood flow. $Sjvo_2$ monitoring has had a major effect on ventilatory management of head-injured patients and has significantly reduced the routine use of hyperventilation in neurosurgical patients.[169-172] $Sjvo_2$ values of less than 50% generally indicate cerebral ischemia. Increases in $Sjvo_2$ may occur in response to therapy, or they may be an ominous sign if the increase is caused by falling demand because of neuronal death.

Similar to $Sjvo_2$ monitoring, monitoring of $P_{Br}o_2$ and blood flow is used most frequently in patients with traumatic brain injury. $P_{Br}o_2$ performs well in clinical practice. Decreases to less than 10 to 15 mm Hg are associated with worsening outcome,[22,173] whereas $P_{Br}o_2$-targeted treatment strategies may improve outcome.[174]

TCD ultrasound is widely used in the intensive care unit to document the presence and severity of cerebral vasospasm after subarachnoid hemorrhage. As the major cerebral arteries narrow, flow velocity within the lumen must increase if blood flow is to be maintained. Such narrowing occurs 12 to 24 hours before the onset of clinical symptoms, thus allowing therapy to be initiated before the onset of clinical symptoms.[175-179] Mean flow velocities of more than 120 cm/s seem to correlate well with angiographic vasospasm,[180,181] although intracranial pressure and concurrent therapy to raise cerebral perfusion pressure modify the flow velocity. The latter two factors result in characteristic changes of the TCD waveform, however, and preserve the utility of the examination.

Prognosis in Coma and Determination of Brain Death

EEG monitoring may help to assess the clinical course and the prognosis of comatose patients. Assessment of prognosis must be separated from the insult that precipitated the coma by more than 24 hours. If not, the EEG may reflect predominantly the effect of the insult and may not predict prognosis. More than 24 hours after the insult, spontaneous sustained burst suppression correlates strongly with severe irreversible brain injury.[182] Absence of EEG variability portends a high likelihood of persistent vegetative state or death,[182,183] whereas spontaneous variability, reactivity to external stimuli, and typical sleep patterns are associated with more favorable outcomes.[184-186]

A specific indication for EEG monitoring is the therapeutic induction of a coma by barbiturate administration. Because neither blood nor cerebrospinal fluid concentrations of barbiturates reliably predict burst suppression and near-maximal reduction in cerebral metabolic rate of oxygen consumption,[187] and because barbiturate administration usually requires an increase in cardiovascular support, documentation of a burst suppression pattern on EEG allows the use of the minimal effective dose of barbiturate.

Similar to EEG, evoked potential studies have a place in predicting prognosis in comatose patients.[188] The presence of normal SSEPs bilaterally is an excellent prognostic sign, whereas the absence of any SSEP cortical response is a poor prognostic indicator. The degree of bad outcome can be predicted by BAEPs. Intact and normal BAEPs with absent cortical SSEPs predict a best outcome of a chronic vegetative state. Outcome may be worse, however, because BAEPs commonly deteriorate later with rostral-to-caudal deterioration. Absent BAEP responses beyond wave I predict a high likelihood of brain death. Present but abnormal SSEPs are associated with outcomes intermediate between good to high function and a chronic vegetative state.[189-198]

TCD ultrasound also has been used in the intensive care unit as an aid to the diagnosis of brain death. As intracranial pressure increases, the pulsatility of the TCD waveform increases, accentuating the systolic peak and diminishing flow during diastole. With further increases in intracranial pressure, a characteristic to-and-fro pattern of flow is established, which is consistent with clinical brain death.[199] TCD studies are easily performed at the bedside and can minimize the need for unnecessary transports of the patient for definitive radiologic studies.

Nonsurgical Factors Influencing Monitoring Results

ANESTHESIA AND THE ELECTROENCEPHALOGRAM

Anesthetic drugs affect the frequency and amplitude of EEG waveforms. Although each drug class and each specific drug has some specific, dose-related EEG effects (Table 39.3), some basic anesthesia-related EEG patterns may be described. Subanesthetic doses of intravenous and inhaled anesthetics usually produce an increase in frontal beta activity and abolish the alpha activity normally seen in the occipital leads in an awake, relaxed patient with the eyes closed. As the patient loses consciousness with general anesthesia, the brain waves become larger in amplitude and slower in frequency. In the frontal areas, small beta activity seen in an awake patient slows to the alpha range and increases in size. In combination with the loss of the occipital alpha activity, this phenomenon produces the appearance of a “shift” of the alpha activity from the posterior cortex to the anterior cortex. Further increases in the dose of inhaled or intravenous anesthetic drugs produce further slowing of the EEG. Some anesthetic drugs suppress EEG activity totally (see Table 39.3). Other anesthetic drugs never produce burst suppression or an isoelectric EEG, despite increasing dose, either because they are incapable of completely suppressing the EEG (e.g., opioids, benzodiazepines) or because cardiovascular toxicity of the drug (e.g., halothane) prevents administration of a large enough dose.

Intravenous Anesthetic Drugs

Barbiturates, Propofol, and Etomidate. Despite widely varying potencies and durations of action, barbiturates, propofol, and etomidate produce similar EEG patterns (Fig. 39.18 shows EEG effects of thiopental). These drugs all follow the basic anesthesia-related EEG pattern described previously with initial EEG activation (see Fig. 39.18A), followed by dose-related depression. As the patient loses consciousness, characteristic frontal spindles are seen (see Fig. 39.18B), which are replaced by polymorphic 1- to 3-Hz activity (see Fig. 39.18C) as the drug dose is increased. Further increases in dose result in lengthening periods of suppression interspersed with periods of activity (burst suppression). With a very high dose, EEG silence results. All of these drugs have been reported to cause epileptiform activity in humans, but epileptiform activity is clinically significant only after methohexital and etomidate when given in subhypnotic doses.

Ketamine. Ketamine does not follow the basic anesthesia-related EEG pattern. Anesthesia with ketamine is characterized by frontally dominant rhythmic, high-amplitude theta activity. Increasing doses produce intermittent polymorphic delta activity of very large amplitude interspersed with low-amplitude beta activity.[200] Electrocortical silence cannot be produced with ketamine. EEG activity may be very disorganized and variable at all doses. This disorganization of the EEG with ketamine is responsible for the failure of the bispectral index (BIS) to be useful in looking at the effect of ketamine on consciousness.[201] Recovery of normal EEG

TABLE 39.3 Anesthetic Drugs and Electroencephalogram

Drug	Effect on EEG Frequency	Effect on EEG Amplitude	Burst Suppression?
Isoflurane, Sevoflurane, Desflurane			Yes, >1.5 MAC
Subanesthetic	Loss of alpha, ↑frontal beta		
Anesthetic	Frontal 4-13 Hz activity		
Increasing dose >1.5 MAC	Diffuse theta and delta → burst suppression → silence	↓0	
Nitrous oxide (alone)	Frontal fast oscillatory activity (>30 Hz)	↓, especially with inspired concentration >50%	No
Barbiturates			Yes, with high doses
Low dose	Fast frontal ↑ beta activity	Slight	
Moderate dose	↑Frontal alpha frequency spindles		
Increasing high dose	Diffuse delta → burst suppression → silence	↓0	
Etomidate			Yes, with high doses
Low dose	Fast frontal beta activity		
Moderate dose	Frontal alpha frequency spindles		
Increasing high dose	Diffuse delta → burst suppression → silence	↓0	
Propofol			Yes, with high doses
Low dose	Loss of alpha; frontal beta		
Moderate dose	Frontal delta; waxing/waning alpha		
Increasing high dose	Diffuse delta → burst suppression → silence	↓0	
Ketamine			No
Low dose	Loss of alpha, variability	↓	
Moderate dose	Frontal rhythmic delta		
High dose	Polymorphic delta; some beta	Beta is low amplitude	
Benzodiazepines			No
Low dose	Loss of alpha; increased frontal beta activity		
High dose	Frontally dominant delta and theta		
Opioids			No
Low dose	Loss of beta; alpha slows	None	
Moderate dose	Diffuse theta, some delta		
High dose	Delta, often synchronized		
Dexmedetomidine	Moderate slowing, prominent spindles		No

Alpha =8-13 Hz frequency; beta =>13 Hz frequency; delta =<4 Hz frequency; theta = 4-7 Hz frequency. *EEG*, Electroencephalogram; *MAC*, minimum alveolar concentration.

activity even after a single bolus dose of ketamine is slow compared with barbiturates. There is no information available about the relationship between emergence reactions after ketamine and the EEG. Ketamine also has been associated with increased epileptiform activity.[200]

Benzodiazepines. Despite varying potencies and durations of action, benzodiazepines also follow the basic anesthesia-related EEG pattern. As a class, however, these drugs are incapable of producing burst suppression or an isoelectric EEG.

Opioids. As a class, opioids do not follow the basic anesthesia-related EEG pattern. Opioids generally produce a dose-related decrease in frequency and increase in amplitude of the EEG. If no further doses of opiates are given, alpha and beta activity return as drug redistribution occurs. The rapidity of return depends on the initial dose and on the drug. In rats, remifentanil is associated with the most rapid return to normal.[202] Complete suppression of the EEG cannot be obtained with opioids. Epileptiform activity occurs in humans and in animals receiving large to supraclinical doses of opioids. Sharp wave activity is common after induction of anesthesia with fentanyl, with 20% of patients showing this phenomenon after 30 μg/kg; 60%, after 50 μg/kg; 58%, after 60 μg/kg; and 80%, after 70 μg/kg.[203] Alfentanil bolus has been used clinically to activate seizure foci during epilepsy surgery.[204] This epileptiform activity is mainly noted in the frontotemporal region.

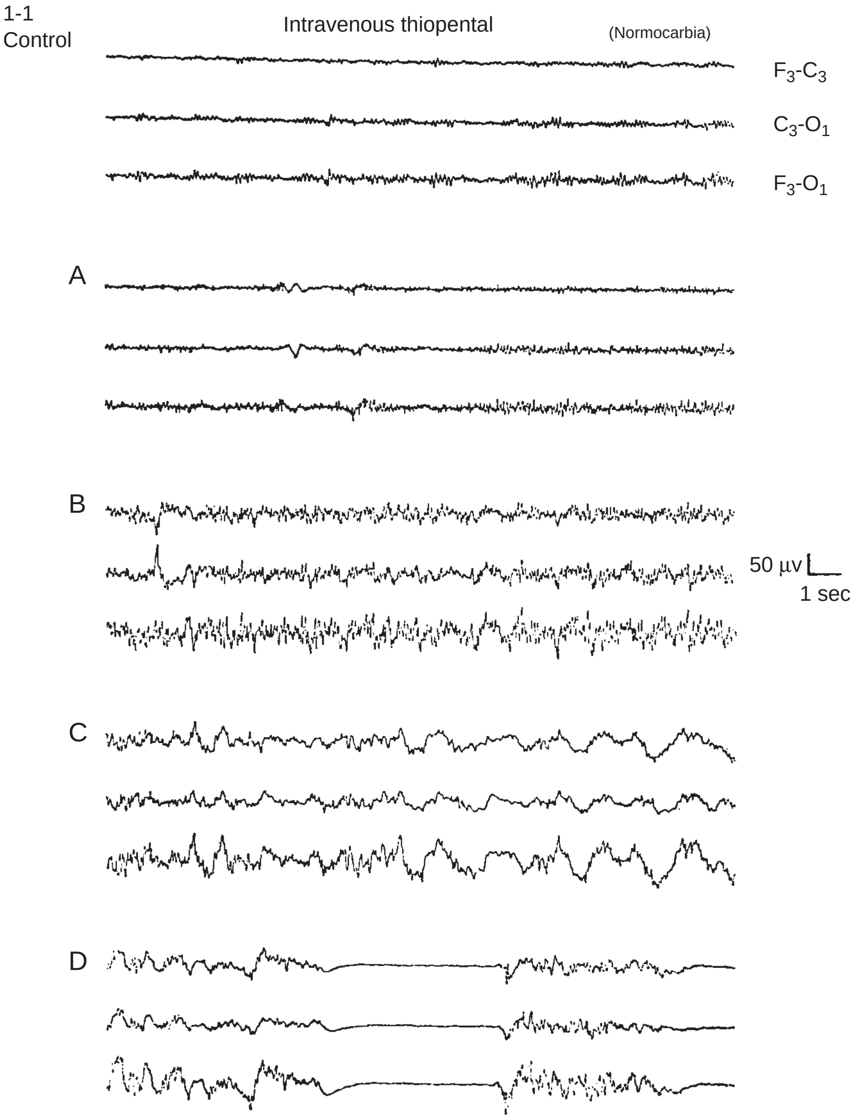

Fig. 39.18 Electroencephalogram effects of intravenous administration of thiopental in humans. (A) Rapid activity. (B) Barbiturate spindles. (C) Slow waves. and (D) Burst suppression. (From Clark DL, Rosner BS. Neurophysiologic effects of general anesthetics. *Anesthesiology.* 1973;38:564.)

Dexmedetomidine. Dexmedetomidine is being increasingly used for sedation in the operating room and in the intensive care unit, and is also used for sedation during diagnostic EEG studies in children. EEG studies of patients undergoing sedation with dexmedetomidine alone show patterns similar to those seen in normal human sleep with increased slow-wave activity and sleep spindles prominent.[205] Burst suppression or an isoelectric EEG pattern cannot be produced even with high doses of the drug. Level of sedation with dexmedetomidine can be effectively monitored using processed EEG parameters and has been reported using BIS and entropy techniques.[206] Interestingly, BIS values at comparable levels of sedation appear to be lower with dexmedetomidine than propofol.[207]

Inhaled Anesthetics

Nitrous Oxide. Used alone, nitrous oxide causes a decrease in amplitude and frequency of the dominant occipital alpha rhythm. With the onset of analgesia and depressed consciousness, frontally dominant fast oscillatory activity (>30 Hz) is frequently seen.[208] This activity may persist to some extent for 50 minutes after discontinuation of nitrous oxide. When nitrous oxide is used in combination with other agents, it increases the effects that would be associated with the agent alone clinically and with respect to the EEG pattern seen.

Isoflurane, Sevoflurane, and Desflurane. Potent inhaled anesthetic drugs, including halothane and enflurane, which are no longer available, follow the basic anesthesia-related EEG pattern. Isoflurane initially causes an activation of the EEG followed by a slowing of the EEG activity that is more marked with increasing dose. Isoflurane begins to produce periods of EEG suppression at 1.5 MAC, which become longer with increasing dose until electric silence is produced at 2 to 2.5 MAC. Isolated epileptiform patterns sometimes can be seen during intersuppression activity at 1.5 to 2 MAC isoflurane.[209] Sevoflurane causes similar dose-dependent EEG effects. Equi-MAC concentrations of sevoflurane and isoflurane

TABLE 39.4 Ability of an Individual Anesthetic Drug to Produce a Change in Sensory- and Motor-Evoked Potentials That Could Be Mistaken for a Surgically Induced Change

cause similar EEG changes.[210] Epileptiform activity has been induced by administration of sevoflurane in patients without epilepsy, and seizure activity on EEG, but not clinical seizure activity, has been reported in pediatric patients with a history of epilepsy during induction of anesthesia with sevoflurane.[211,212] Despite these observations, sevoflurane, similar to other inhalation drugs, is not suitable for use during electrocorticography for localization of seizure foci.[213] EEG patterns seen with enflurane are similar to the patterns seen with isoflurane except that epileptiform activity is considerably more prominent. At 2 to 3 MAC, burst suppression is seen, but virtually all intersuppression activity consists of large spike/wave pattern discharges. Hyperventilation with high concentrations of enflurane increases the length of suppression, decreases the duration of bursts, but increases the amplitude and main frequency component of the intersuppression epileptiform activity. Frank EEG seizures also may occur with enflurane that produce the same cerebral metabolic effects as pentylenetetrazol, a known convulsant.

Halothane also produces EEG patterns similar to those of isoflurane, but dosages of halothane that would produce burst suppression in the EEG (3-4 MAC) are associated with profound cardiovascular toxicity. Desflurane produces EEG changes similar in nature to equi-MAC concentrations of isoflurane. In limited clinical studies, there has been no evidence of epileptiform activity with desflurane, despite hyperventilation and 1.6 MAC dosage,[214] and desflurane has been used as a treatment of refractory status epilepticus.[215]

Clinical studies have shown that the EEG effects of inhaled anesthetic drugs are influenced by age and baseline EEG characteristics. Older patients and patients with EEG slowing at baseline were more sensitive to the EEG effects of isoflurane and desflurane. As anesthesia was deepened, similar EEG pattern changes were noted, but these changes occurred at lower end-tidal anesthetic concentrations.[216]

BOX 39.1 Guidelines for Choosing Anesthetic Techniques During Procedures in Which Sensory-Evoked Responses Are Monitored

1. Intravenous drugs have significantly less effect than "equipotent" doses of inhaled anesthetics
2. Combinations of drugs generally produce "additive" effects
3. Subcortical (spinal or brainstem) sensory-evoked responses are very resistant to the effects of anesthetic drugs. If subcortical responses provide sufficient information for the surgical procedure, anesthetic technique is not important, and effects on cortically recorded responses may be ignored

ANESTHESIA AND SENSORY-EVOKED RESPONSES

Volatile Anesthetics

Multiple drugs used in the perioperative period can influence the ability to monitor SERs accurately (Table 39.4). An extensive review from 2003 provides the interested clinician with a detailed analysis of all drug effects on SERs,[217] which is beyond the scope of this chapter. Table 39.4 does not quantify drug effects, but rather lists whether an individual drug is capable of producing a change in any part of an evoked response that could be mistaken for a surgically induced change. A "no" designation in this table does not mean that there are no effects of a given drug on SERs. The "no" designation indicates that any effects that do occur would not be called clinically significant by *clinicians experienced in intraoperative monitoring*. Several general concepts (Box 39.1) help the clinician who is trying to determine the best choice of drugs for use during monitored cases.

The volatile anesthetics isoflurane, sevoflurane, desflurane, enflurane, and halothane have similar effects in differing degrees on all types of SERs. VEPs are the most sensitive

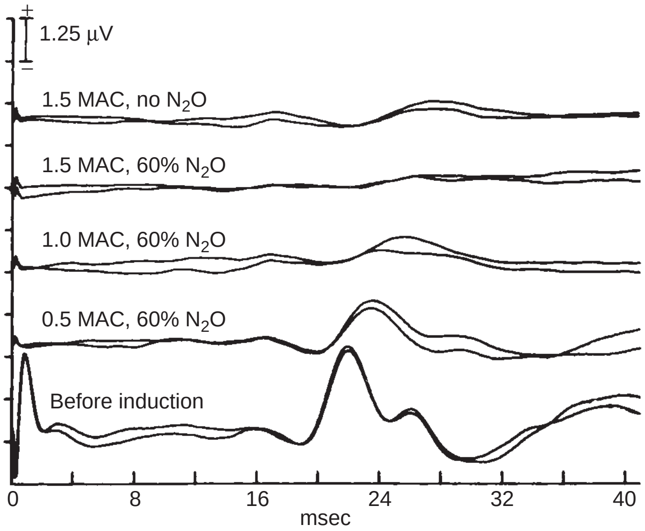

Fig. 39.19 **Representative somatosensory-evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration *(MAC)* levels of isoflurane.** (From Peterson DO, Drummond JC, Todd MM. Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory-evoked potentials in humans. *Anesthesiology*. 1986;65:35.)

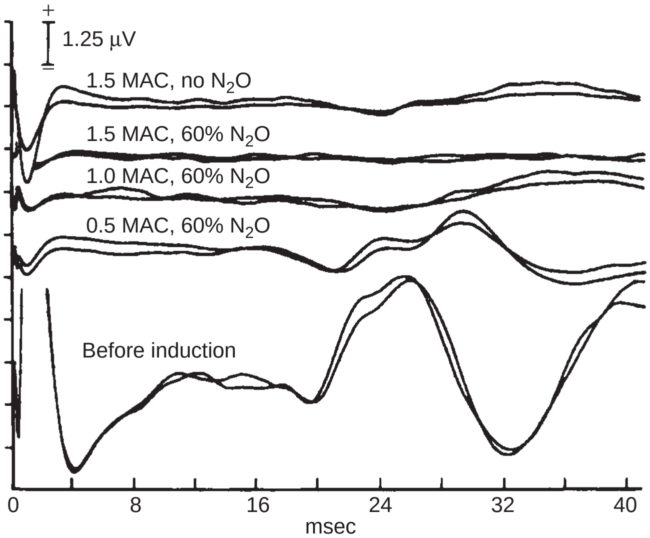

Fig. 39.20 **Representative somatosensory-evoked potential cortical responses (C-3, or C-4-FPz) at various minimum alveolar concentration *(MAC)* levels of enflurane.** (From Peterson DO, Drummond JC, Todd MM. Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory-evoked potentials in humans. *Anesthesiology*. 1986;65:35.)

to the effects of volatile anesthetics, and BAEPs are the most resistant to anesthetic-induced changes. Spinal and subcortical SSEP responses are significantly less affected than cortical potentials.[218-220]

SSEPs, because they are the most widely used intraoperative SER technique, are the most completely studied with respect to the effects of anesthetic drugs. The effects of the currently used volatile anesthetics on cortical SSEPs are dose-dependent increases in latency and conduction times and a decrease in amplitude of cortically, but not subcortically recorded signals.[221] When comparing the different volatile agents, studies have reported conflicting results.[218,220] None of these differences are clinically important and may be ignored by the practicing clinician. With respect to the newer agents, desflurane and sevoflurane seem to have qualitatively and quantitatively similar effects on SERs as isoflurane.[222-225] In neurologically normal patients, 0.5 to 1 MAC of any of the potent inhaled agents in the presence of nitrous oxide is compatible with monitoring of cortical SSEPs (Figs. 39.19–39.21).[217] Neurologically impaired patients may show a significantly greater sensitivity to inhaled agents, even to the point of not tolerating any recordable level of inhaled agent. Generally, better monitoring conditions are obtained, however, with narcotic-based anesthetics with less than 1 MAC total (nitrous oxide plus potent agent) end-tidal inhaled anesthetic concentration.

The volatile anesthetics result in increases in latency of BAEPs without significantly affecting the amplitude.[226-228] Volatile anesthetics cause increases in latency and decreases in amplitude in the early (middle latency) cortical responses after auditory stimulation,[227] however, and these middle latency responses are now being used to monitor the hypnotic component of general anesthetics.[228] Adequate monitoring of BAEPs is possible with any clinically useful concentrations of inhaled agents (with or without nitrous oxide) (Figs. 39.22 and 39.23).

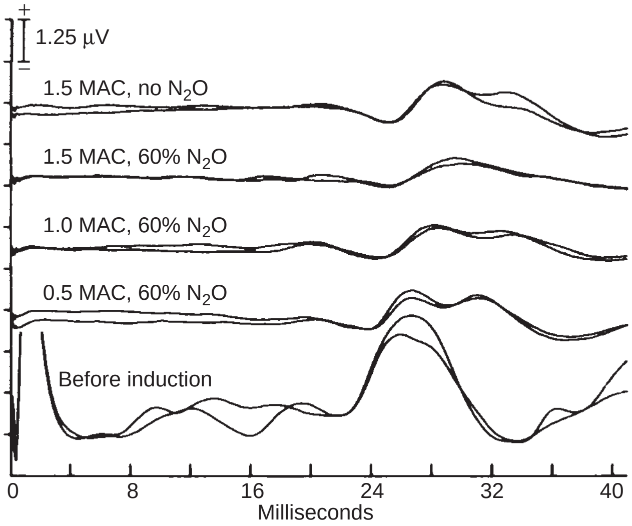

Fig. 39.21 **Representative somatosensory-evoked potential cortical responses (C-3, C-4-FPz) at various minimum alveolar concentration *(MAC)* levels of halothane.** (From Peterson DO, Drummond JC, Todd MM. Effects of halothane, enflurane, isoflurane, and nitrous oxide on somatosensory-evoked potentials in humans. *Anesthesiology*. 1986;65:35.)

Use of the volatile anesthetic drugs during monitoring of VEPs results in dose-dependent increases in latency with or without changes in amplitude.[229] Isoflurane results in dose-dependent increases in latency and decreases in amplitude up to 1.8% in 100% oxygen, at which time the waveform is lost.[221] More recent studies report some success in recording intraoperative VEPs from patients with normal eyesight, but waveform variability and potent depression of waveforms by volatile agents remain concerns.[230,231] In the opinion of many experts, the variability of VEPs in anesthetized patients is so great that satisfactory monitoring is impossible using any anesthetic technique.

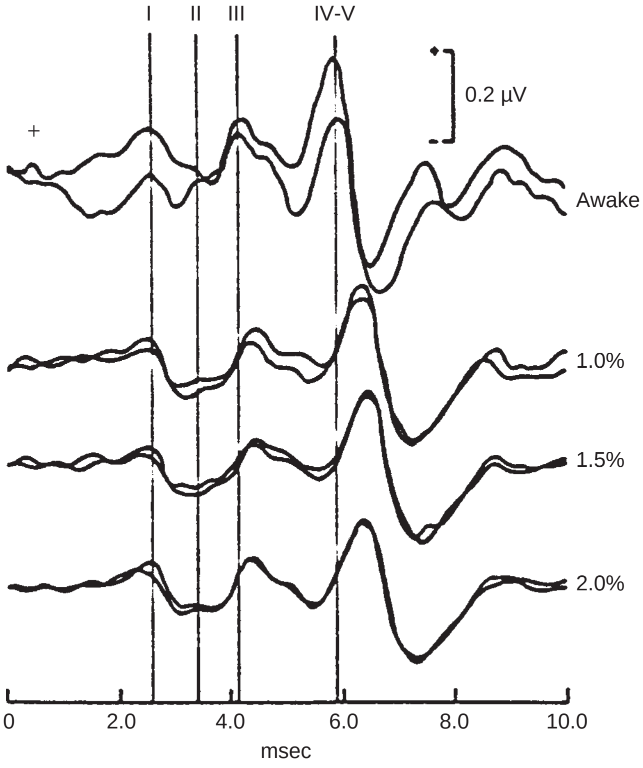

Fig. 39.22 Influence of isoflurane alone on brainstem auditory-evoked potential in a typical subject. Latency of peaks III and IV to V increased at 1.0% but stabilized with increasing anesthetic depth. (From Manninen PH, Lam AM, Nicholas JF. The effects of isoflurane–nitrous oxide anesthesia on brainstem auditory evoked potentials in humans. *Anesth Analg*. 1985;64:43.)

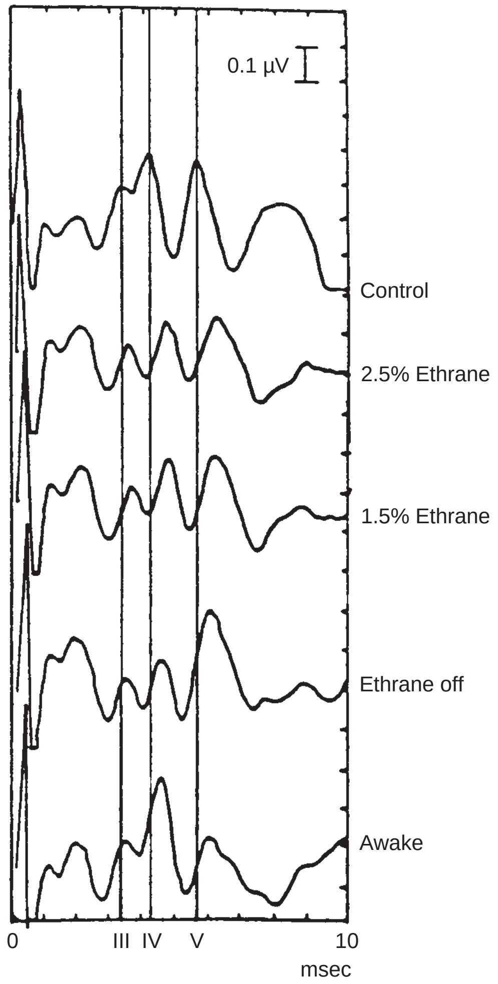

Fig. 39.23 Brainstem auditory-evoked potential recording obtained in one patient at different enflurane (Ethrane)-inspired concentrations. (From Dubois MY, Sato S, Chassy J, et al. Effects of enflurane on brainstem auditory evoked responses in humans. *Anesth Analg*. 1982;61:898.)

Although volatile anesthetics cause significant changes in the SER waveforms, it is possible to provide adequate monitoring intraoperatively in the presence of anesthetic doses of volatile anesthetics. Doses of anesthetic drugs causing significant depression of the response to be monitored must be prevented. In our experience, end-tidal concentrations of inhaled anesthetic drugs totaling greater than 1.3 MAC have a dose-related, increasing probability of obliterating cortical SSEPs even in neurologically normal patients. Equally important, anesthetic concentration should not be changed during the critical periods of intraoperative monitoring. Critical periods are defined as periods in which surgical interventions are most likely to result in damage to neurologic tissue and changes in the SERs. Because the volatile anesthetic-induced changes in SERs are dose dependent, increasing anesthetic dosage at a crucial point in the operative procedure can result in confusing changes in the SERs that potentially may be caused by the anesthetic, the surgical procedure, or both. The appropriate intervention is difficult to determine.

As with the volatile anesthetics, nitrous oxide causes differing effects on the SERs depending on the sensory system monitored. It causes decreases in amplitude without significant changes in latency in SSEPs when used alone or when added to a narcotic-based or volatile anesthetic.[217,218,232] The addition of nitrous oxide to a maintenance volatile anesthetic during the monitoring of BAEPs causes no further change.[226] Likewise, use of nitrous oxide alone causes no change in BAEPs, unless gas accumulates in the middle ear.[232] Use of nitrous oxide alone results in an increase in latency and a decrease in amplitude in VEPs, but when it is added to a volatile anesthetic technique, it causes no further changes in VEPs.[229,232]

Intravenous Anesthetics

The effects of propofol on SERs have been studied in many different settings. At typical clinical doses required for general anesthesia, propofol has minimal effects on somatosensory-evoked responses recorded along the somatosensory pathway up to the early cortical potentials.[233,234] Thus propofol-based TIVA is frequently used as the preferred technique to optimize signal-to-noise ratio for SSEPs and provide rapid feedback to the surgeon.[235] BAEPs under propofol anesthesia show minor increases in interpeak latencies and decreases in amplitude that are insufficient to interfere with clinical monitoring of auditory function.[236,237]

The effects of barbiturates on SERs have been studied in animals and humans. Increasing doses of thiopental in patients result in progressive dose-dependent increases in latency, decreases in amplitude of SSEPs, and progressive increases in latency of wave V in BAEPs. The changes in SSEPs are more pronounced than the changes in BAEPs, and waveforms beyond the initial primary cortical response are quickly obliterated. This finding is consistent with the theories that barbiturates affect synaptic transmission more than axonal conduction. Early waveforms in SERs result primarily from axonal transmission, and later waves depend on multisynaptic pathways in addition to axonal transmission. At doses of thiopental far greater than doses producing an isoelectric EEG, adequate monitoring of early cortical and subcortical SSEPs and BAEPs was preserved.[238] Other barbiturate compounds show similar effects.[239] This observation is important, especially when attempting to monitor the adequacy of CBF during cerebrovascular surgery when the patient has been given large, "protective" doses of barbiturates. The EEG is isoelectric and not helpful for monitoring. The early cortical SSEP waveforms are still preserved, however, and may be very helpful in determining adequacy of CBF. Preserved ability to monitor SSEPs in head-injured patients receiving therapeutic thiopental infusions has been demonstrated.[240] VEPs are much more sensitive to barbiturates. Low barbiturate doses obliterate all except the earliest waveforms. In cats, the early potentials persisted with increases in latency even to very high pentobarbital doses.[241] Except for VEPs, adequate perioperative monitoring of SERs is possible even in the presence of high-dose barbiturate therapy as long as the effects of the drug (increased latency with moderately decreased amplitude) are considered.

After bolus administration and intravenous infusions, etomidate causes increases in latency of all waves and prolongation of central conduction time in SSEPs. In contrast to virtually all other commonly used anesthetics, etomidate causes increases in amplitude of the cortical SSEP.[242,243] This effect may be due to an alteration in the balance of inhibitory and excitatory influences or an increase in the irritability of the CNS. This effect seems to be present in the cortex, but not in the spinal cord. Etomidate infusions have been used to enhance SSEP recording in patients when it was impossible to obtain reproducible responses at the beginning of intraoperative monitoring because of the pathology (Fig. 39.24). Following baseline responses that could not be monitored, the etomidate augmentation of the SSEP allowed adequate monitoring and detection of intraoperative events leading to compromise of the spinal cord.[243] The effects of etomidate on BAEPs are dose-dependent increases in latency and decreases in amplitude that are not clinically significant.[244]

Benzodiazepines also can cause changes in SERs.[245,246] Diazepam causes increases in latency and decreases in amplitude of SSEPs, increases in latency in the cortical response after auditory stimulation, and no change in BAEPs. Midazolam causes decreases in amplitude without changes in latency of SSEPs.[242]

Generally, opioids cause small dose-dependent increases in latency and decreases in amplitude of SSEPs. These changes are not clinically significant. Effects on amplitude are more variable than the latency increases.[247,248] Even at large doses of fentanyl (60 µg/kg), reproducible SSEPs can be recorded. Other opioids cause similar dose-dependent changes in SSEPs.[249] Opioids can be used even in high doses in patients requiring intraoperative SSEP monitoring without impairment of ability to monitor neurologic function adequately. Opioid-induced changes must be taken into account, however, when evaluating the recordings. Large intravenous bolus administration of opioids should be avoided at times of potential surgical compromise to neurologic function to prevent confusing the interpretation of SEP changes if they develop. BAEPs were resistant to doses of fentanyl of 50 µg/kg with no changes observed in absolute latency, interpeak latency, or amplitude.[250]

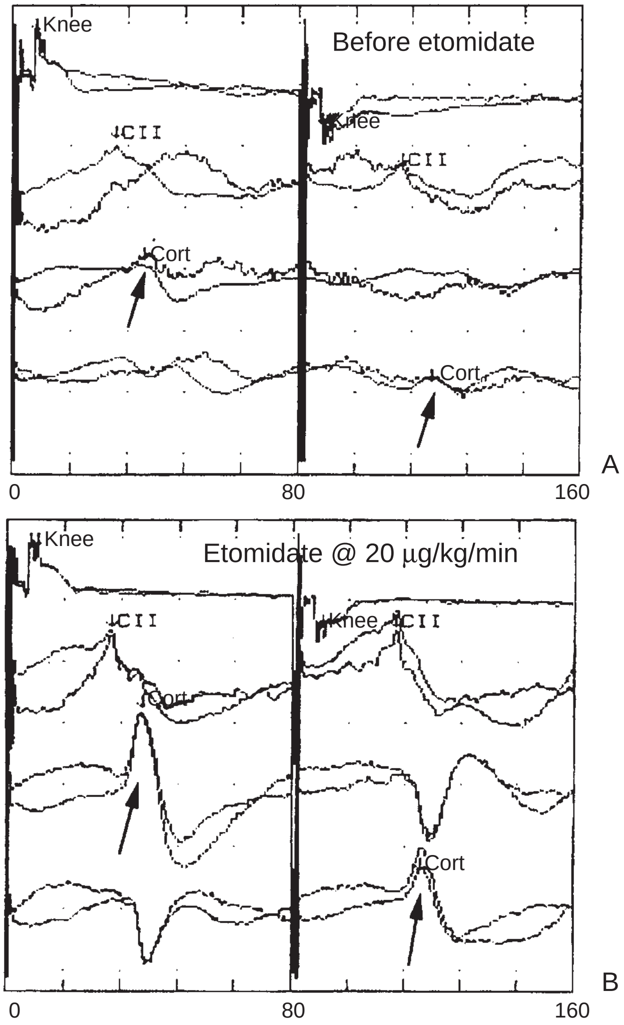

Fig. 39.24 Effects of etomidate on somatosensory-evoked potential. (A) These tracings were obtained from a mildly mentally impaired patient with severe kyphoscoliosis during the early maintenance phase of anesthesia using isoflurane and fentanyl. (B) These tracings were obtained after discontinuing isoflurane and instituting an etomidate infusion at 20 µg/kg/minute. Note dramatically increased amplitude and clarity of the signal in the cortical *(Cort)* channels (marked by *arrows*), which both are recorded with the same amplification scale.

Based on several case reports and small series, dexmedetomidine is compatible with all types of evoked potential monitoring,[251] although data regarding MEPs are not entirely consistent. One recent study demonstrated significant attenuation of MEPs during scoliosis surgery when dexmedetomidine was used as an adjunct to propofol and remifentanil.[252] Data are limited, and large studies are lacking entirely. As the use of this drug increases, more data should become available, but at this time, use of dexmedetomidine does not seem to be clearly problematic.

ANESTHESIA AND MOTOR-EVOKED POTENTIALS

Effects of anesthetics on tcMEPs recorded from muscle are surprisingly profound (see Table 39.4).[253-257] Anesthetic techniques typically used by most anesthesiologists for spine surgery would produce prohibitive depression of the MEP.[258,259] Investigators showed in several studies that intravenous anesthetic drugs produce significantly less depression, and techniques using any of a combination of ketamine, opiates, etomidate, and propofol have been described.[255,256,260-263] The authors have had excellent experience with a combination of propofol and remifentanil, which also is supported in the literature.

Anesthetic effects on MEP responses recorded at spinal levels seem to be less serious. When responses are recorded from muscle, neuromuscular blocking drugs should be monitored quantitatively, maintaining T1 twitch height at around 30% of control values to prevent excessive movement during the operation.[126,254] When responses are not recorded from muscle, profound relaxation is desirable because gross muscle movement produced by MEP stimulation is eliminated, facilitating the surgical procedure. More recent studies using rapid trains of stimuli with transcranial electric and magnetic stimulus techniques have produced responses that are more resistant to the effects of anesthetic drugs, and more "traditional" techniques using inhaled anesthetics and narcotics may be used.[263-265] Most studies support the use of TIVA as preferable to techniques using nitrous oxide or potent inhaled anesthetic drugs, however. Precise control of the anesthetic and avoidance of boluses during critical monitoring periods seem to be even more important than for SSEPs, and active cooperation of the anesthesia care team is essential for good, reproducible results. Fig. 39.25 shows the dramatic effect of introduction of 0.3 MAC isoflurane to a total intravenous technique using propofol and remifentanil. Given ability to monitor the hypnotic component of a TIVA technique with several different available monitors, the authors recommend a total intravenous technique without relaxant whenever possible.

Fig. 39.25 (A) Transcranial electrical motor-evoked potential recording showing surgically induced change during spine surgery (scoliosis repair). (B) Motor-evoked potential with an anesthetic-induced change. Note similarity of the change pattern, except that in the anesthetic-induced change, the responses in the upper extremity also changed. Left-sided and right-sided responses are shown on the corresponding panel. A single upper extremity response is shown (top tracing) in each panel. Responses from four muscle groups in each lower extremity are shown directly below. *Ant tib,* M tibialis anterior; *gast,* m gastrocnemius; *L,* left; *quad,* m quadriceps femoris; *R,* right; *then,* thenar.

PATHOPHYSIOLOGIC EFFECTS ON THE ELECTROENCEPHALOGRAM

Hypoxia

Hypoxia may produce inadequate delivery of oxygen to the cerebral cortex generating EEG, and changes similar to those occurring with ischemia result. Initially, hypoxemia may not result in any EEG changes because the brain can increase blood flow to compensate. When the hypoxemia becomes severe enough, further increases in flow are impossible, and EEG changes occur. "Slowing" of the EEG during hypoxia is a nonspecific global effect. Fast frequencies are lost, and low frequencies dominate. Eventually, the EEG is abolished as the brain shuts down electric activity and diverts all oxygen delivered to maintenance of cellular integrity.

Hypotension

In a normal, awake patient, significant levels of hypotension are needed to cause the earliest of CNS signs, as measured by discrimination tests such as the flicker-fusion test. This test examines the flicker rate at which the observer perceives the light to be continuous. In the early days of deliberate hypotension, this test was part of the preoperative evaluation to judge how far the pressure could be reduced during the operation. Clear signs of confusion and inability to concentrate or respond properly to simple commands generally represent very low levels of cerebral perfusion when caused by hypotension because the normal cerebral circulation has a large capacity to vasodilate and maintain normal flow in the face of significant hypotension.

The EEG changes associated with even this level of hypotension are not dramatic, although they are clear by comparison with a previously active recording. Herein lies the problem with using intraoperative EEG to determine whether a given level of hypotension has resulted in brain ischemia. EEG changes are not very pronounced and are bilateral. These changes also are nearly identical to the changes caused by increasing doses of many anesthetic drugs. EEG changes associated with hypotension can be detected, but when the hypotension is induced slowly and associated with changes in anesthetic drugs (e.g., use of isoflurane to reduce blood pressure), the changes are very difficult to interpret. EEG changes associated with acute, severe hypotension such as may be caused by sudden arrhythmias are easier to read. Many patients undergoing surgery do not have a normal cerebral circulation, however. In these individuals, even mild hypotension may result in significant cerebral ischemia. In these individuals, monitoring the EEG during planned hypotension may be helpful, provided that other causes of similar EEG changes may be carefully controlled. There remains little literature to support the use of EEG monitoring during hypotension, but in our opinion, when the EEG is being monitored (e.g., during carotid surgery), EEG changes secondary to hypotension really do represent cerebral ischemia of a significant degree and should be considered an important finding.

Hypothermia

During cooling on CPB, the total power and peak power frequency of the high-frequency band were highly correlated with temperature using Fourier analysis and spectral edge data; however, significant variability was noted among subjects, especially during cooling.[266] Complete EEG suppression usually develops at 15°C to 18°C. Levy and colleagues[147] showed an improved ability to quantify the effects of hypothermia on the EEG using an EEG processing technique known as "approximate entropy."

Hypercarbia and Hypocarbia

Hypocapnia is known to activate excitable seizure foci, and in rare cases may produce EEG evidence of cerebral ischemia even in awake subjects.[267] Hypercapnia, unless severe and associated with hypoxemia, has only indirect effects secondary to increased CBF. In an anesthetized patient, hypercarbia-associated increases in CBF may have similar effects to the effects seen with increasing end-tidal tension of volatile anesthetics.[268]

Untoward Events

One of the suggested reasons for monitoring the brain of an anesthetized patient is to enable detection of injuries to the nervous system that would not be otherwise apparent. Although hundreds of such case reports are in the literature, as well as many in our experience, cost-effectiveness of such monitoring is unclear. In a more recent case at our institution, severe EEG changes occurred at the beginning of a carotid endarterectomy, before surgical incision, and were unassociated with any other vital sign changes or hypotension. Immediate angiography revealed acute carotid occlusion and completely changed the operation performed with this patient, and the patient recovered completely. There are intraoperative events that could lead to CNS insult, which, if detected early, could be rapidly reversed or treated to prevent permanent injury. Given the rarity of such events, however, it is extremely unlikely that such monitoring would be shown to be beneficial in any foreseeable randomized trial. If the "at-risk" patient could be identified preoperatively, perhaps the EEG or other types of neuromonitoring could be useful in detecting untoward CNS events during anesthesia, such as a new stroke after elective general surgery.

PHYSIOLOGIC FACTORS INFLUENCING SENSORY-EVOKED RESPONSES

Numerous physiologic variables, including systemic arterial blood pressure, temperature (local and systemic), and blood gas tensions, can influence SEP recordings. With decreases in mean arterial blood pressure to below levels of cerebral autoregulation owing to either blood loss or vasoactive drugs, progressive changes in SERs have been noted. SSEP changes observed are progressive decreases in amplitude until loss of the waveform with no changes in latency.[269,270] BAEPs are resistant to even profound levels of hypotension (MAP of 20 mm Hg in dogs).[269] Cortical (synaptic) function necessary to produce cortical SERs seems to be more sensitive to hypoperfusion than spinal cord or brainstem, nonsynaptic transmission.[270] Rapid decreases in arterial blood pressure to levels above the lower limit of autoregulation also have been associated with transient SSEP changes of decreased amplitude that resolve after several minutes of continued hypotension at the same level.[271] Reversible SSEP changes at systemic pressures within the normal range have been observed in patients undergoing spinal distraction during scoliosis surgery. These changes resolved with increases of systemic arterial blood pressure to slightly higher than the patient's normal pressure, suggesting that the combination of surgical manipulation with levels of hypotension generally considered "safe" could result in spinal cord ischemia.[272]

Changes in temperature also affect SERs. Hypothermia causes increases in latency and decreases in amplitude of cortical and subcortical SERs after all types of stimulation.[273-275] Hyperthermia also alters SERs, with increases in temperature leading to decreases in amplitude in SSEPs and loss of SSEPs at 42°C during induced hyperthermia.[276]

Changes in arterial blood gas tensions can alter SERs, probably in relation to changes in blood flow or oxygen delivery to neural structures.[277,278] Hypoxia produces SSEP changes (decreased amplitude) similar to the changes seen with ischemia.[278] Decreased oxygen delivery associated with anemia during isovolemic hemodilution results in progressive increases in latency of SSEPs and VEPs that become significant at hematocrit values lower than 15%. Changes in amplitude were variable until very low hematocrit values (approximately 7%) were reached, at which point the amplitude of all waveforms decreased.[279]

Summary

Regardless of the type of intraoperative neurologic monitor, several principles must be observed for neurologic monitoring to provide potential benefit to the patient. First, the pathway at risk during the surgical procedure must be amenable to monitoring. Second, if evidence of injury to the pathway is detected, some intervention must be possible. If changes in the neurologic monitor are detected, and no intervention is possible, although the monitor may be of prognostic value, it does not have the potential to provide direct benefit to the patient from early detection of impending neurologic injury. Third, the monitor must provide reliable and reproducible data. If the data have a high degree of variability in the absence of clinical interventions, their utility for detecting clinically significant events is limited.

This chapter reviews the most common clinically used intraoperative neurologic monitors. Ideally, clinical studies would provide outcome data on the efficacy of a neurologic monitor in a given procedure to improve neurologic outcome. Although there is a wealth of clinical experience with many of these monitoring modalities, there is little in the way of randomized prospective studies evaluating the efficacy of neurologic monitoring. Based on clinical experience with neurologic monitoring and nonrandomized clinical studies in which neurologic monitoring is used and generally compared with historical controls, practice patterns for use of neurologic monitoring have developed. In certain procedures, neurologic monitoring is recommended and used by most centers; in other procedures, monitoring is used almost routinely in some centers, but not in others; and in some procedures, no clear clinical experience or evidence indicates that monitoring is useful at all (experimental use). Finally, there are procedures in which monitoring is used selectively for patients believed to be at higher-than-usual risk for intraoperative neurologic injury. Table 39.5 provides a summary of current clinical practice.

TABLE 39.5 Current Practices in Neurologic Monitoring

Procedure	Monitors	Current Practice
Carotid endarterectomy	Awake patient neurologic examination, EEG, SSEP, TCD	NIH recommends use of one of these four available monitors
	CO	Threshold value not determined, inadequate normative population data
Scoliosis surgical treatment	SSEP	Monitoring recommended and may substitute for wake-up testing
	Wake-up test	Largely abandoned in centers using electrophysiologic monitoring; monitoring is not continuous, and false-negative monitoring patterns reported
	MEP	Increased clinical use now that transcranial electrical stimulation is FDA approved; useful in combination with SSEP
Acoustic neuroma	Facial nerve monitor	Facial nerve monitoring recommended
	BAEP	BAEP showing some clinical evidence of improved outcome in some procedures
Intracranial aneurysm clipping	SSEP, EEG, tcMEP	Used routinely in some centers; limited clinical data on outcome, but appears clinically useful during anterior circulation procedures
Cranial nerve V decompression	BAEP	Used in some centers; reduces hearing loss
Cranial nerve VII decompression	BAEP, facial nerve monitor	Data from small series showing improved hearing preservation
Supratentorial mass lesions	SSEP, tcMEP	Used in some centers in selected high-risk procedures
Infratentorial mass lesions	BAEP, SSEP, tcMEP	BAEP to detect retractor-related cranial nerve VIII injury; SSEP and tcMEP in rare, high-risk lesions adjacent to ascending sensory or descending motor pathways
Decompression of spinal stenosis	SSEP, tcMEP	Used in some centers in high-risk procedures (more often cervical)
Spinal cord trauma	SSEP, MEP	Used in some centers in high-risk procedures
Cardiopulmonary bypass	EEG, TCD, $Sjvo_2$, CO	Used routinely in some centers; actively studied, but no outcome data yet
Aortic coarctation	SSEP	Used routinely in a few centers; no widespread acceptance
Aortic aneurysm repair	SSEP, MEP	Used routinely in a few centers; no widespread acceptance

BAEP, Brainstem auditory-evoked potential; *CO,* cerebral oximetry; *EEG,* electroencephalogram; *FDA,* U.S. Food and Drug Administration; *MEP,* motor-evoked potential; *NIH,* National Institutes of Health; *$Sjvo_2$,* jugular bulb venous oxygen saturation; *SSEP,* somatosensory-evoked potential; *TCD,* transcranial Doppler; *tcMEP,* transcranial motor-evoked potential.

Monitoring the State of the Brain and Central Nervous System During General Anesthesia and Sedation

EMERY N. BROWN, PATRICK L. PURDON, OLUWASEUN AKEJU, and KEN SOLT

KEY POINTS

- Anesthesiologists rely extensively on physiologic signals and anesthetic dosing strategies to infer and to track states of the brain and central nervous system under general anesthesia.
- Heart rate and systemic arterial blood pressure changes are the principal physiologic signals used to monitor the anesthetic state of patients receiving general anesthesia.
- Use of the neurologic examination during induction of and emergence from general anesthesia can provide information regarding loss and recovery of consciousness.
- Electroencephalogram (EEG)–based indices are used to track the level of unconsciousness of patients receiving general anesthesia. The most commonly used EEG-based indices are the bispectral index (BIS), the Patient Safety Index (PSI), Narcotrend, and Entropy.
- Real-time analysis of the unprocessed EEG and the spectrogram (density spectral array) is a highly informative way to monitor the level of unconsciousness of patients receiving general anesthesia.
- Use of the unprocessed EEG and spectrogram for real-time monitoring of the level of unconsciousness is made possible by the fact that the EEG oscillations of anesthetized patients change systematically with anesthetic dose, with anesthetic class (mechanism of action), and patient age.
- Anesthetic-induced oscillations are one of the primary mechanisms through which these agents induce altered arousal states such as sedation and unconsciousness. Therefore, real-time monitoring of the unprocessed EEG and the spectrogram provide a scientifically based, practical, and patient-specific way to track sedation and unconsciousness in the operating room.
- Normalized symbolic transfer entropy (NSTE) is an approach for quantifying how changes in frontoparietal functional connectivity relate to anesthesia-induced changes in consciousness.
- In the future, closed-loop anesthetic delivery (CLAD) systems may provide highly accurate ways to control states of general anesthesia, medical coma, and sedation.
- Obtaining reliable quantitative markers of nociception is an active area of investigation.

General anesthesia is a drug-induced reversible condition composed of four behavioral and physiologic states: antinociception, unconsciousness, amnesia, immobility; and stability of the physiologic systems, including the autonomic, cardiovascular, respiratory, and thermoregulatory systems.[1-3] Continuously monitoring the status of the patient during general anesthesia is crucial for safe and proper delivery of anesthesia care. The physiologic state of the patient under general anesthesia is commonly monitored using the electrocardiogram and an arterial blood pressure cuff, or an arterial catheter, to monitor the cardiovascular system. In more complex cases, a central venous catheter can be used to monitor central venous pressures, and a pulmonary artery catheter can be placed to monitor cardiac output and pressures in the heart and pulmonary circulation. Transesophageal echocardiography can be used intermittently to gain direct visual information about the anatomy and function of the heart. The capnogram provides a continuous readout of the level of expired carbon dioxide and respiration. In intubated patients, more detailed information about the state of the lungs can be acquired from the pressure and volume tracings on the ventilator. The pulse oximeter estimates the level of hemoglobin saturation in the arterial blood, and the thermometer tracks body temperature. Muscle relaxation, or immobility, is monitored primarily using a train-of-four stimulation device, and more grossly by observing changes in muscle tone or movement.

Monitoring the behavioral states is more challenging. During general anesthesia, amnesia is not monitored directly but implicitly by the extent to which unconsciousness is achieved. If the patient is unconscious and not simply conscious but unresponsive, the patient will likely have amnesia. In this chapter, we discuss approaches for monitoring unconsciousness and analgesia, or more accurately stated antinociception, and each of the three phases of general anesthesia: induction, maintenance, and emergence. This chapter's focus is on physiologic signs and neurologic examination findings, and the electroencephalogram (EEG)–based measures, used to track these states of general anesthesia.

Induction of General Anesthesia

Monitoring of a patient's level of consciousness begins at induction of general anesthesia. Induction is usually achieved by an intravenous bolus dose of a hypnotic drug such as propofol, a barbiturate, ketamine, or etomidate. Unconsciousness usually occurs in 10 to 30 seconds. The brain state of the patient, which in this case is the transition into unconsciousness, is tracked by monitoring the patient's physiologic signs and the EEG-based index.

PHYSIOLOGIC SIGNS OF LOSS OF CONSCIOUSNESS

When a hypnotic drug is administered to induce general anesthesia—usually as an intravenous bolus over a 5- to 10-second period—several physiologic signs are observed. If asked to count backwards from 100, the patient typically does not get beyond 85 to 90. This transition into unconsciousness can be followed easily by asking the patient to perform smooth pursuit of the anesthesiologist's finger.[1] In smooth pursuit, the patient is instructed to move his or her eyes to track the position of the anesthesiologist's finger. As loss of consciousness ensues, the lateral excursions of the eyes during smooth pursuit decrease, nystagmus may appear, blinking increases, and the eyes fix abruptly in the midline. The oculocephalic reflex and the corneal reflex are lost, but the pupillary response to light can remain intact. The patient typically becomes apneic, atonic, and unresponsive at the point when the oculocephalic reflex is lost.

The oculocephalic reflex is assessed by turning the patient's head from side to side, while lifting the eyelids. Before administration of the induction anesthetic, when the reflex is intact in a patient with no neurologic deficits, the eyes move in the direction opposite the motion of the head. When the reflex is lost, the eyes stay fixed in the midline.[4] The oculocephalic reflex requires the circuits of cranial nerves III, IV, VI, and VIII to be intact. The motor nuclei associated with cranial nerves III and IV are located in the midbrain, whereas the nucleus of cranial nerve VI is located in the pons. The corneal reflex has traditionally been assessed using a wisp of cotton at the corner of the eye to stroke the cornea. An easier way to assess the reflex is to allow a drop of sterile water to fall on the cornea. Using a drop of sterile water may be safer than using the wisp of cotton, because the former is less likely to cause a corneal abrasion. With either approach, the reflex is intact if the eyes blink consensually, is impaired if there is a blink in one eye and not the other, and is absent if there is no blink. The afferent component of the corneal reflex travels to the sensory nucleus of the cranial nerve V through the ophthalmic branch, whereas the efferent component arises from the motor nucleus of the cranial nerve VII. The nuclei for these nerves associated with the oculocephalic reflex and the corneal reflex lie in close proximity to the arousal centers in the midbrain, pons, hypothalamus, and basal forebrain.[4]

Loss of the oculocephalic reflex suggests that the motor nuclei required for eye movements have been affected by the anesthetic. Similarly, loss of the corneal reflex suggests that the nuclei that control sensation and motor responses to sensation on the eyes and the face have also been affected. Because the loss of the oculocephalic and corneal reflexes occur concomitantly with the loss of responsiveness, the anesthesiologists can also infer that the loss of consciousness is due at least in part to the effects of the anesthetics on the nearby arousal centers.[1,4,5] Apnea, which commonly occurs on induction of general anesthesia with bolus administration of a hypnotic agent, is most likely due to the inhibitory effects of the anesthetic on the dorsal and ventral respiratory groups in the medulla and pons, respectively.[6] Atonia can be due to anesthetic action at any one of multiple sites in the motor pathways between the primary motor areas and the spinal cord. The most likely brainstem sites are the pontine and medullary reticular nuclei.[2]

Loss of the oculocephalic reflex, the corneal reflex, apnea, and atonia occur concomitantly with loss of consciousness on induction of general anesthesia because of the actions of the hypnotic drug in the brainstem after an intravenous bolus. Blood containing the anesthetic reaches the brainstem through the basilar artery, which supplies the posterior cerebral arteries that provide the posterior input to the circle of Willis.[5] Before terminating in the posterior cerebral arteries, the basilar artery runs on the dorsal surface of the brainstem and gives off multiple penetrating arteries that perfuse the brainstem nuclei with the anesthetic leading to the observed physiological effects.

ELECTROENCEPHALOGRAM-MARKERS OF LOSS OF CONSCIOUSNESS

EEG-based indices are among the most commonly used methods for tracking loss of consciousness induced by general anesthesia.[7] With induction of general anesthesia, these indices usually change from high values that indicate the awake state to lower values that indicate states of sedation and unconsciousness.

Maintenance of General Anesthesia: Physiologic Signs and the Nociceptive-Medullary-Autonomic Pathway

Despite the many advances in anesthesia care, the physiologic signs of changes in heart rate, arterial blood pressure, and movement are the measurements most commonly used to track the anesthetic state during maintenance of general anesthesia.[8] When the state of general anesthesia is not adequate for the level of surgical (nociceptive) stimulation, heart rate and arterial blood pressure can increase dramatically. The changes in heart rate and arterial blood pressure that anesthetized patients show in response to a nociceptive stimulus can be explained in terms of the nociceptive-medullary-autonomic (NMA) circuit composed of the spinoreticular tract, the brainstem arousal circuits, and the sympathetic and parasympathetic efferent pathways (Fig. 40.1).[1,9] It is important to understand how the NMA circuit works because it is the pathway most used by anesthesiologists for monitoring the patient's level of unconsciousness and antinociception. One example is a description of the NMA pathway in a clinical context that is commonly observed in the operating room.

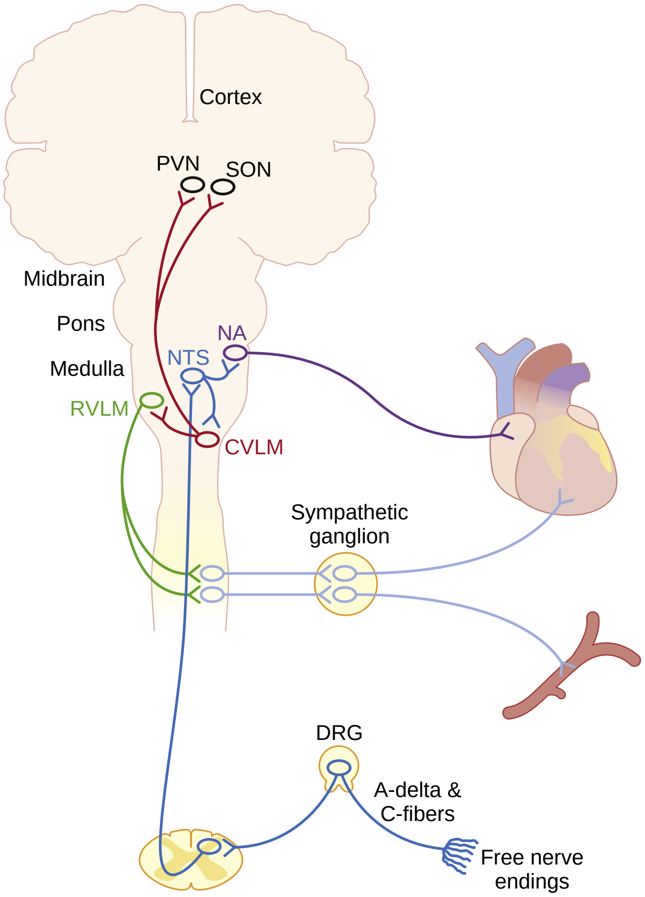

Fig. 40.1 Nociceptive medullary autonomic circuit. The ascending nociceptive (pain) pathway starts with C fibers and A-delta peripheral afferent fibers that synapse on projection neurons (PNs) in the dorsal horn. The PNs cross the midline, course to the brain where they synapse at several targets, including the nucleus of the tractus solitarius *(NTS)* in the medulla. The NTS mediates the autonomic response to a nociceptive stimulus by increasing sympathetic output through the rostral ventral lateral medulla *(RVLM)* and the caudal ventral lateral medulla *(CVLM)*, which projects to the thoracolumbar sympathetic ganglia. The ganglia project to peripheral blood vessels and the heart. The nucleus ambiguous *(NA)* mediates the parasympathetic output to the sinoatrial node of the heart through the vagus nerve. The NTS projects also to the supraoptic nucleus *(SON)* and periventricular nucleus *(PVN)* in the hypothalamus. The NMA circuit is the reason why anesthesiologists use increases in blood pressure and heart rate as markers of increases in nociceptive stimulation and, possibly, a level of general anesthesia that is inadequate. *DRG,* Dorsal root ganglion. (Redrawn from Brown EN, Lydic R, Schiff ND. General anesthesia, sleep, and coma. *N Engl J Med.* 2010;363:2638–2650.)

Suppose that a patient is in a stable state of general anesthesia when, to gain better exposure, the surgeon moves the retractor. Suppose also that this maneuver induces an immediate increase in heart rate and arterial blood pressure. Assuming, that there are no occult hemodynamic or respiratory problems or other common issues that increase heart rate and arterial blood pressure, then these increases likely occurred because the level of general anesthesia did not maintain an adequate level of antinociception. By simultaneously monitoring, in addition, the level of muscle relaxation and oxygen saturation, and oxygen delivery, along with EEG-based indices to track level of unconsciousness, the anesthesia provider can determine that these increases are due to inadequate antinociception and decide to administer more analgesic.

The ascending nociceptive (pain) pathway begins with A-delta and C-fibers whose free nerve endings bring nociceptive information from the periphery to the spinal cord (see Fig. 40.1).[10] In the spinal cord, these fibers synapse in the dorsal horn on projection neurons that travel through the anterolateral fasciculus and synapse at multiple sites in the brainstem, including the nucleus of the tractus solitarius in the medulla.[1,9] The autonomic response to a nociceptive stimulus is initiated from the nucleus of the tractus solitarius, which mediates sympathetic output through the rostral ventral lateral medulla and the caudal ventral lateral medulla to the heart and peripheral blood vessels through projections to the thoracolumbar sympathetic ganglia.[1] The parasympathetic output from the nucleus of the tractus solitarius is mediated through the nucleus ambiguous, which projects through the vagus nerve to the sinoatrial node of the heart.[1] The nucleus of the tractus solitarius also projects to the periventricular nucleus and supraoptic nucleus in the hypothalamus. Thus the nociceptive stimulus of moving the retractor initiates an increase in sympathetic output and a decrease in parasympathetic output through the NMA circuit that rapidly results in the observed increases in heart rate and arterial blood pressure.

The NMA circuit explains why increases in heart rate and arterial blood pressure are used as a rapid indicator of an inadequate level of antinociception. If unconsciousness is sufficiently well maintained, then no EEG changes will likely be observed. If no acute changes in physiology occur for other reasons, such as bleeding, hypoxemia, disconnection of the breathing circuit, or inadequate dosing of the muscle relaxant, the appropriate treatment is administration of more analgesic medication.

Activity in the NMA circuit can be observed rapidly when a patient is under general anesthesia,[11] because this pathway is a fundamental component of the fight-or-flight response.[12] This circuit is used as a sentinel for detecting nociceptive stimuli that can lead to autonomic, stress, and arousal responses. Heart rate and arterial blood pressure changes are the principal markers of activity under general anesthesia because motor responses are often blocked by muscle relaxation. Neurologists frequently test the NMA circuit with nociceptive stimuli, such as total body pinches, nail bed pinches, and sternal rubs, to evaluate the level of arousal of patients with brain injuries that affect the level of consciousness.[4,13,14]

Other signs of inadequate antinociception are perspiration, tearing, pupil dilation, and return of muscle tone and movement.[8] Changes in muscle tone and movement are not observed if the patient is receiving a muscle relaxant. The galvanic skin response has also been studied as a potentially more objective measure of antinociception. However, it is not used in clinical practice.[15]

Maintenance of General Anesthesia: Electroencephalogram-Based Indices of Level of Consciousness

It is widely recognized that the EEG changes systematically in relation to the dose of anesthetic drug administered (Fig. 40.2).[1,7,16-18] As a consequence, the unprocessed EEG and

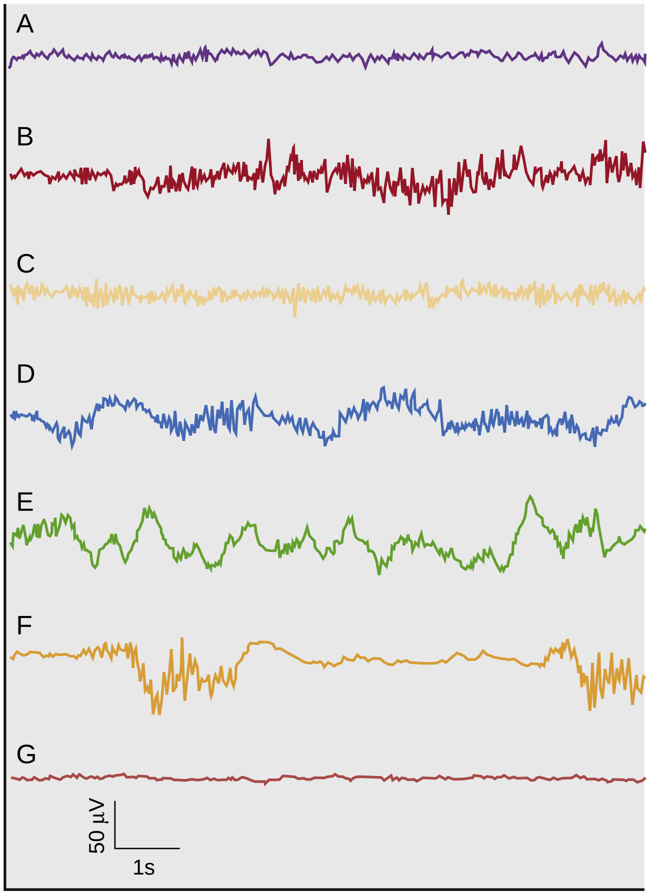

Fig. 40.2 Anesthetic states and electroencephalogram signatures of propofol. (A) Awake electroencephalogram pattern with eyes open. (B) State of paradoxical excitation. (C) Beta (13-25 Hz) oscillations frequently associated with an arousable state of sedation. (D) Slow (0.1-1 Hz), delta (1-4 Hz), and alpha (8-12 Hz) oscillations commonly seen during unconsciousness at surgical planes. (E) Slow oscillations typically recorded during propofol induction and during deep dexmedetomidine sedation (see Fig. 40.8, *D*). (F) Burst suppression, a state of profound anesthetic-induced brain inactivation, seen commonly in the elderly during normal maintenance, anesthetic-induced coma, and hypothermia. (G) Isoelectric electroencephalogram pattern commonly observed in brief periods during normal maintenance, in anesthetic-induced coma, and profound hypothermia.

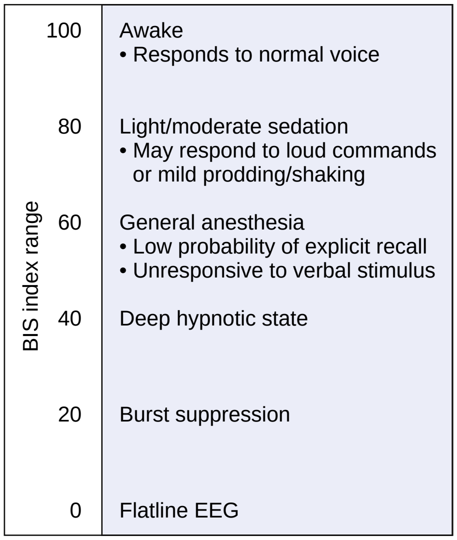
various forms of processed EEG have been used to track the level of unconsciousness of patients receiving general anesthesia and sedation. Several EEG-based index systems have been studied and used in clinical practice. These systems process the EEG and provide an index value or set of values in real time or near real time that can be used to track the level consciousness. In general, the indices are designed to decrease with decreasing level of consciousness and increase as consciousness returns. In this way, the anesthesia provider can use these indices along with the physiological signs to track the patient's state of unconsciousness and, to some degree, antinociception. A summary of the EEG-based indices that have received the most use in clinical practice and clinical studies follows.



BIS index range
100
80
60
40
20
0
Awake
• Responds to normal voice
Light/moderate sedation
• May respond to loud commands or mild prodding/shaking
General anesthesia
• Low probability of explicit recall
• Unresponsive to verbal stimulus
Deep hypnotic state
Burst suppression
Flatline EEG

Fig. 40.3 Anesthetic states and the bispectral index *(BIS)*. The chart provides a behavioral interpretation of the values of the BIS. *EEG*, Electroencephalogram. (Redrawn from Kelley SD. *Monitoring Consciousness: Using the Bispectral Index*. 2nd ed. Boulder, CO: Covidien; 2010.)

BISPECTRAL INDEX

The bispectral index (BIS) is an empirically derived scale that was proposed in 1994 by Aspect Medical Systems (later acquired by Covidien [Boulder, Colorado] and lastly by Medtronic [Minneapolis, Minnesota]) as a novel way to monitor anesthetic state in patients receiving general anesthesia and sedation.[19,20] The algorithm processes the EEG in near real time and computes an index value between 0 and 100 that indicates the patient's anesthetic state (Fig. 40.3).[21,22] A value of 100 corresponds to being completely awake, whereas 0 corresponds to a profound state of coma or unconsciousness that is reflected by an isoelectric or flat EEG. The BIS algorithm is proprietary, and the actual computation through which the index is derived is not public knowledge. However, it is known that BIS combines information from three EEG analyses: the spectrogram, the bispectrum, and a time domain assessment of burst suppression.[21-23] The spectrogram is a decomposition of the EEG into its power content by frequency as a function of time.[21] The bispectrum measures the degree of nonlinear coupling between pairs of frequencies in the spectrogram.[21] The BIS algorithm works by measuring specific features of the spectrogram, the bispectrum, and the level of burst suppression, and uses a predetermined weighting scheme to convert these features into the index value. The EEG also undergoes various artifact corrections. Along with the index value, the unprocessed EEG, the spectrogram, and the level of electromyographic activity are displayed on the monitor. Production of the index is computationally intensive, so that there is a 20- to 30-second lag between the time the EEG is observed and the computation of the corresponding BIS value.[24] A patient is considered to be appropriately anesthetized (i.e., unconscious) when the value of the BIS is between 40 and 60 (see Fig. 40.3).[22,25] The EEG is recorded from a four-lead frontal montage.

Since its approval by the US Food and Drug Administration (FDA) in 1996, the BIS monitor has been studied extensively in clinical trials and used widely in anesthesiology practice. The changes in the index are correlated with the level of sedation and unconsciousness (see Fig. 40.3), primarily because for many anesthetics, the EEG shows lower-frequency, higher-amplitude oscillations as patients achieve deeper states of unconsciousness (see Fig. 40.2). Three exceptions are the anesthetics ketamine, nitrous oxide, and dexmedetomidine. The dissociative anesthetic state produced by ketamine is associated with prominent high-frequency oscillations rather than slow wave oscillations.[26] As a consequence, patients can be unconscious with ketamine but have high index values.[27]

The effect of nitrous oxide on the BIS index is ambiguous. Most recent studies state that nitrous oxide increases the amplitude of high-frequency EEG activity[28] and decreases the amplitude of low-frequency EEG activity,[29] yet it has little to no effect on the BIS index.[22,30] However, these studies have not taken into account the state of profound transient large-amplitude slow oscillations, followed by lower amplitude gamma oscillations that have now been documented to be common features observed when nitrous oxide is administered in high-dose (>50%).[31] In the case of dexmedetomidine, slow oscillations and an appreciable decrease in beta oscillation power[32,33] are prominent during sedation.[34-36] These dynamics most likely lead to BIS values that are typically in the unconscious range, even though the patient can be aroused by verbal commands or light shaking.

As we discuss in the "Changes in EEG Signatures with Aging" section, anesthetic-induced EEG oscillations change systematically with age.[26,37] BIS appears to work poorly in older adults (>60), as patients in this age cohort tend to have lower amplitude oscillations, which the BIS algorithm can interpret as an awake state or state of unconsciousness. Similarly, the BIS algorithm is known to inaccurately reflect the anesthetic state of children because they generally have much more power across a broader range of frequency bands when appropriately anesthetized compared with adults in the 18 to 59 year age range.[37,38] Hence, even though the children may be well anesthetized, the BIS algorithm provides numbers suggesting a state of sedation rather than unconsciousness.

Use of the BIS monitor has been proposed as a way to prevent intraoperative awareness, which is defined as the patient having explicit recall of events that transpired during the time that he or she was under general anesthesia. Use of the BIS monitor as a way to prevent intraoperative awareness was studied in the B-Aware Trial.[39] This study compared patients at high risk for awareness who were randomly assigned to monitoring with BIS using a target range of 40 to 60 and patients monitored with the standard of care at that particular institution. The patients in the BIS group had a significantly lower incidence of awareness.

The findings from this study were called into question because of several design concerns, and for this reason the B-Unaware Trial was conducted.[40] The B-Unaware Trial was a multicenter investigation that randomly assigned patients to either BIS monitoring or monitoring of the end-tidal anesthetic gas concentration to compare the two approaches for preventing awareness. The end-tidal gas concentration was maintained between 0.7 and 1.3 of the age-adjusted minimum alveolar concentration (MAC) of the anesthetic administered to the patient (discussed under End-Tidal Anesthetic Concentration). As in the B-Aware Trial, the objective in the BIS-monitored group was maintenance of the BIS value between 40 and 60. This study found no significant difference in the incidence of awareness among the patients monitored with BIS compared with those monitored with the end-tidal gas concentration. The authors interpreted these findings to mean that BIS monitoring was not more effective than the end-tidal anesthetic criterion in preventing awareness in patients receiving general anesthesia using volatile anesthetics. Several concerns were expressed about the findings of this study as well. The most notable were subject selection and whether the study had sufficient power to detect actual differences, had they been present.[41,42]

As a follow-up to this study, the investigators in the B-Unaware Trail conducted the BIS or Anesthetic Gas to Reduce Explicit Recall (BAG-RECALL) trial, a second trial investigating whether BIS was superior to the end-tidal anesthetic gas concentration in preventing intraoperative awareness in a larger group of patients at high risk for awareness.[41] In this trial, the investigators found that the BIS-guided protocol was not superior to the end-tidal anesthetic concentration-guided protocol in preventing awareness. Because the B-Unaware trial and the BAG-RECALL trial used inhaled anesthetics as the primary agents, their conclusions do not apply to patients receiving total intravenous anesthesia.

Preventing awareness under general anesthesia is a solvable problem if strategies used to monitor the brain states of patients use markers that relate directly rather than indirectly to the mechanisms through which the anesthetics act at specific receptors and neural circuits to alter level of arousal.[1,43,44] Unlike the current EEG-based indices, these markers will differ with patient age and different anesthetics, (See the Unprocessed EEG and the Spectrogram section).

PATIENT SAFETY INDEX

The Patient Safety Index (PSI) is like the BIS index—a proprietary algorithm that assesses anesthetic state based on the EEG for patients receiving general anesthesia or sedation. The PSI was approved by the FDA in 2000 and was originally developed by Physiometrix (North Billerica, Massachusetts), and was ultimately acquired by Masimo (Irvine, California). The development of the PSI was the outgrowth of several years of research conducted by E. Roy John at the Brain Research Laboratory at the New York University School of Medicine.[45] Like the BIS index, the PSI is also scaled between 0 and 100 (Fig. 40.4). However, the PSI range to ensure that the patient is unconscious is between 25 and 50.[46]

The original formulation of the PSI used an electrode montage that included occipital and frontal EEG leads to monitor the phenomenon of anteriorization as a marker of change in anesthetic state. Anteriorization is the forward shift of spectral power from the occipital area to the frontal area during loss of consciousness and the posterior shift of this power from the frontal areas to the occipital areas during the return of consciousness.[44,47-49] The current formulation of the PSI uses a four-lead frontal EEG montage. In addition to displaying the PSI, this monitor also shows

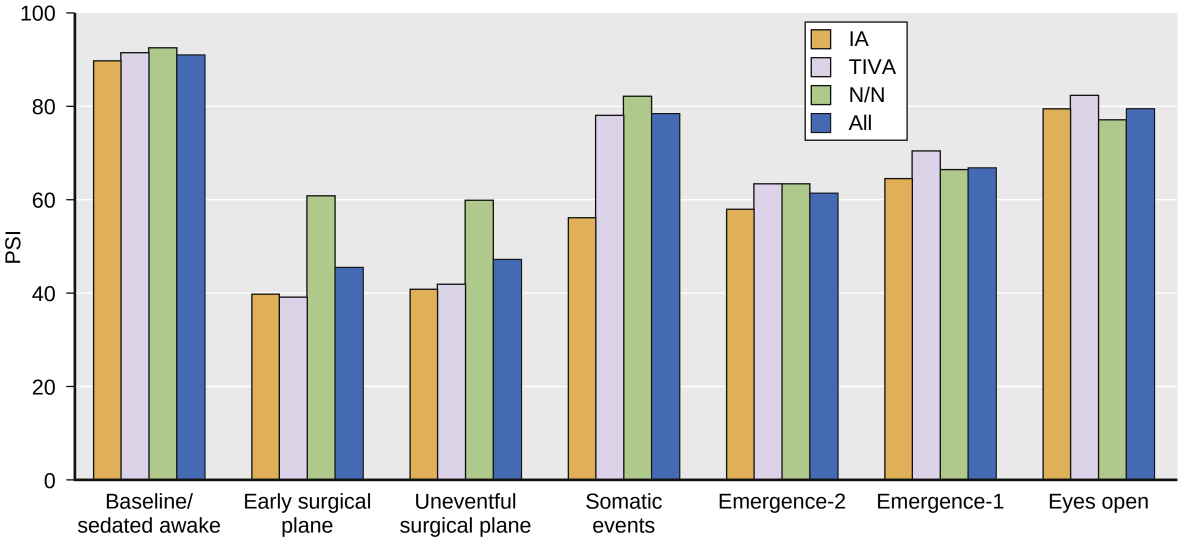


Fig. 40.4 Anesthetic states and the patient safety index *(PSI)*. The histogram provides the anesthetic state interpretation of the values of the PSI. *IA*, Inhaled anesthetics; *N/N*, nitrous narcotic; *TIVA*, total intravenous anesthesia. (Redrawn from Drover D, Ortega HR. Patient state index. *Best Pract Res Clin Anaesthesiol.* 2006;20:121–128.)

in real time the unprocessed EEG and its spectrogram from both the left and right sides of the head, the level of electromyographic activity, an artifact index, and the suppression ratio. The suppression ratio is a number between 0 and 100 that measures the fraction of time the EEG is in burst suppression. The monitor also allows the user to change the viewing screen among various combinations of the unprocessed EEG traces, the spectrogram, and the time series of the PSI values.

In head-to-head comparisons, the PSI correlates strongly with the BIS readings in terms of tracking a patient's anesthetic state.[50-52] This monitor has been less frequently studied in clinical investigations and has not received the same level of clinical use as the BIS monitor. In our experience, the PSI can also give ambiguous information for ketamine, nitrous oxide, dexmedetomidine, and pediatric patients.

NARCOTREND

The Narcotrend, produced by MonitorTechnik (Bad Bramstedt, Germany), is an EEG-based device designed to monitor the anesthetic state in patients receiving general anesthesia or sedation.[53] This monitor was developed at the University Medical School of Hanover, Germany, and has been approved by the FDA for use in the United States for patient care. Like the BIS and PSI, the Narcotrend uses a proprietary algorithm that converts the EEG into different states, denoted as *A* to *F* (Table 40.1).[54] Stage A corresponds to the patient being wide-awake, whereas stage F corresponds to increasing burst suppression down to an isoelectric state. The newer version of the Narcotrend monitor includes a Narcotrend Index, which is scaled between 0 and 100.[51] In addition, the Narcotrend monitor displays the unprocessed EEG signal and its spectrogram. This monitor has also been validated with respect to the BIS index and separately. Its performance has been variable.[24,55,56] Narcotrend has received less clinical use than BIS and PSI.

TABLE 40.1 Anesthetic States, the Narcotrend Stages, and Narcotrend Index Ranges

	Narcotrend Stage	Narcotrend Index
Awake	A B_0	95-100 90-94
Sedated	B_1 B_2	85-89 80-84
Light anesthesia	C_0 C_1 C_2	75-79 70-74 65-69
General anesthesia	D_0 D_1 D_2	57-64 47-56 37-46
General anesthesia with deep hypnosis	E_0 E_1 E_2	27-36 20-26 13-19
General anesthesia with increasing burst suppression	F_0 F_1	5-12 1-4

The table provides the anesthetic state interpretation of the Narcotrend Stages and the Narcotrend Index values.

ENTROPY

The use of entropy to track the anesthetic state of patients is a relatively new monitoring approach. Entropy is a well-known concept in the physical sciences, mathematics, and information theory. Entropy measures the degree of disorder or the lack of synchrony or consistency in a system.[57] Entropy-based analyses have been applied to the EEG and have been used to construct EEG-based indices meant to indicate the depth of anesthesia. The Entropy monitor was developed by Datex-Ohmeda, which is now part of GE Healthcare (Little Chalfont, United Kingdom). The algorithm in the GE device uses frequency domain analysis,

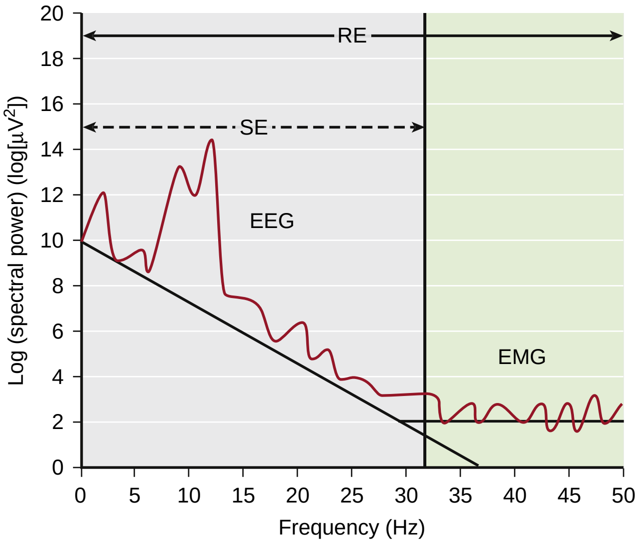

Fig. 40.5 Schematic representation of the spectral entropy. The response entropy *(RE)* is computed from the power in the frequencies between 0 and 47 Hz. The state entropy *(SE)* is computed from the power in the frequencies between 0 and 32 Hz. The power between 32 and 47 Hz is assumed to represent artifacts coming from the electromyogram *(EMG)*. The difference between the RE and SE allows the anesthesiologist to distinguish between electroencephalogram *(EEG)* changes related to changes in the anesthetic state and changes that are due to artifact or movement. (Redrawn from Bein B. Entropy. *Best Pract Res Clin Anaesthesiol.* 2006;20:101–109.)

combined with burst suppression to measure the entropy of the EEG in patients receiving anesthetic drugs. Unlike several of the other algorithms we have discussed, the entropy algorithm used in the GE entropy device is publicly available.[58,59]

A readily apparent feature of the EEG, as patients proceed through deeper anesthetic states, is that the patterns become more regular and ordered (see Fig. 40.2). That is, we observe an apparent decrease in the entropy of the EEG signal. The Entropy monitor reports two entropy numbers to aid in interpreting this monitor's EEG analysis (Fig. 40.5).[60] The first is the response entropy (RE) and the second is the state entropy (SE). The RE tracks the changes in the EEG power in the higher frequency range 0.8 to 47 Hz, whereas the SE tracks the changes in the EEG power in the lower frequency range of 0.8 to 32 Hz.[58] The relative changes in the RE and the SE have been proposed as a way to distinguish between real brain state changes versus those that are due to muscle activity on the electromyogram.[58] In general, electromyographic activity shows up in the higher frequency range tracked by the RE. As a patient becomes more profoundly unconscious, the RE declines faster than the SE, thereby making it possible to distinguish unconsciousness from movement artifacts. Monitoring entropy is consistent with changes with the BIS.[61]

Like the BIS, PSI, and Narcotrend, the Entropy scores correlate with anesthetic state. The Entropy monitor, like BIS and the PSI, can show paradoxically high readings for ketamine and nitrous oxide. The Entropy scores can be misleading when the patient is receiving dexmedetomidine, because the highly ordered slow waves that are present commonly during deep sedation with dexmedetomidine do not necessarily indicate a profound state of unconsciousness.

END-TIDAL ANESTHETIC CONCENTRATION

In 1965, Eger and colleagues first introduced the concept of the MAC of an inhaled anesthetic required for immobility (defined as lack of movement in response to noxious stimulation).[62] Five years later, Eger's group also introduced the concept of MAC-awake, or the MAC of inhaled anesthetic necessary to ablate response to a verbal command.[63] The median MAC value (i.e., the MAC of inhaled anesthetic required for immobility in 50% of patients) remains the gold standard for dosing inhaled anesthetics, and some modern anesthesia machines calculate age-adjusted MAC values based on the patient's end-tidal anesthetic gas concentration. However, the ratio of MAC to MAC-awake varies widely among general anesthetics,[64] suggesting that MAC cannot be used to define or predict brain states in anesthetized patients. This has been confirmed by animal experiments demonstrating that there is no clear association between anesthetic-induced EEG patterns and immobility,[65] and that inhaled anesthetics produce immobility primarily through their actions in the spinal cord, rather than the brain.[66,67] Nevertheless, the widely accepted concept of MAC has led to the use of end-tidal anesthetic concentration as a way to monitor anesthetic state induced by inhaled anesthetics.

As mentioned previously, this use of MAC has been supported by the B-Unaware Trial, which reported no difference in the incidence of intraoperative awareness with an anesthetic protocol that maintained the BIS value between 40 and 60, and a protocol that maintained an end-tidal anesthetic concentration between 0.7 and 1.3 MAC.[40] Similarly, the BAG-RECALL Trial limited enrollment to patients at high risk for intraoperative awareness. Patients with BIS-guided general anesthesia experienced a small but statistically significant higher incidence of intraoperative awareness than patients receiving general anesthesia guided by an end-tidal anesthetic criterion.[41]

Unlike the BIS, PI, Entropy, and Narcotrend, which provide EEG-based measures of brain activity, the end-tidal anesthetic concentration is related to brain activity through the concentration of inhaled anesthetic expired in the lungs. This assumes that the lung anesthetic concentration is in equilibrium with the brain concentration. Moreover, this assumes that, except for age adjustment, the same brain concentration in every patient, regardless of brain health or physiological state, defines the same anesthetic state. The end-tidal anesthetic concentration is thus an indirect and less nuanced measure of anesthetic state, given that the relevant effects of the anesthetics for inducing unconsciousness are in the brain and not in the lungs. That an EEG-based criterion and a lung-gas criterion are comparable for monitoring the level of consciousness under general anesthesia suggests more of a flaw in the design of the EEG-based marker, rather than the accuracy of the end-tidal anesthetic concentration. Because it is a more indirect measure of anesthetic state, the success of the end-tidal anesthetic concentration in preventing awareness comes likely at the expense of overdosing some patients. A key drawback of the end-tidal anesthetic concentration is that it cannot be used with total intravenous anesthesia.

OTHER STRATEGIES FOR MONITORING LEVEL OF CONSCIOUSNESS

Other strategies for monitoring level of consciousness during general anesthesia and sedation have been studied. For example, the Cerebral State Monitor,[68] the SNAP Index,[69] and the AEP Index[70] are other EEG-based approaches that have been studied and applied in clinical practice.

Emergence From General Anesthesia

ELECTROENCEPHALOGRAM-BASED INDICES AND RETURN OF CONSCIOUSNESS

As stated earlier, the EEG-based indices typically specify a range for maintenance of anesthetic state (see Figs. 40.3 to 40.5, and Table 40.1). When delivery of the anesthetic drugs is decreased or terminated, the indices increase toward values that are consistent with the awake state. As the values of the indices increase, the patient is more likely to become conscious. In this way, the EEG-based indices can be used to monitor changes in anesthetic state during emergence from general anesthesia. Although the values of the indices increase during emergence, none of the indices has a value at which the patient is certain to regain consciousness. The lack of any mechanistic relationship between the values of the EEG-based index and level of consciousness is due to imprecision in the definition of the indices, in that many different anesthetic states are presumed to map to the same index value. Friedman and colleagues and Joiner and colleagues found that neural inertia can play a role with inhaled anesthetics.[71,72] Neural inertia is the extent to which equal brain concentrations of anesthetic on induction and emergence often yield different behavioral states. In other words, the history of the brain states helps determine arousability.

PHYSIOLOGIC SIGNS AND RETURN OF CONSCIOUSNESS

The state of the patient during emergence from general anesthesia can be tracked reliably by monitoring the patient's physiologic signs and performing neurologic examinations.[1] Many of these physiologic changes relate to the return of brainstem function (Box 40.1). Therefore, by relating the physiologic signs and the findings from the neurologic examinations to the brainstem centers responsible for them, anesthesia providers can track the return of function to specific brainstem sites during emergence from general anesthesia. Once neuromuscular blockade has been reversed, the patient may breathe unassisted. As the level of carbon dioxide in the cerebral circulation increases, most patients begin to breathe spontaneously. As the patient emerges from general anesthesia, the respiratory pattern can transition from one that is irregular with small tidal volumes to one that is regular with full normal tidal volumes.[1] Return of spontaneous breathing is a distinct indicator of return of function in the medulla and lower pons, as these are the locations of the dorsal and ventral respiratory groups, respectively.[6]

Over the ensuing several minutes and often concomitant with the return of spontaneous respiration, a series of other clinical signs begin to appear (see Box 40.1). These signs include swallowing, gagging, salivation, tearing, and grimacing.[1] The signs each represent return of a specific center in the brainstem and the associated sensory and motor pathways. Swallowing, gagging, and coughing represent return of the motor nuclei of the cranial nerves IX and X located in the medulla and the sensory afferent of these nerves arising from the trachea, larynx, and pharynx.[10] These physiologic signs appear because with the progressive decrease in the hypnotic and antinociceptive effects of the anesthetics, the endotracheal tube becomes a progressively more noxious stimulus. Salivation reflects the return of the inferior salivatory nucleus in the medulla and superior salivatory nucleus in the pons. Both are part of the parasympathetic nervous system. The efferent pathways from these nuclei travel in cranial nerves VII and IX, respectively.[9] Tearing also reflects the return of function in the superior salivatory nucleus. Grimacing, the use of muscles of facial expression, represents the return of function to the motor nucleus of cranial nerve VII, located in the pons.[10] Return of muscle tone to the upper and lower extremities is another important clinical sign that clearly reflects return of function in a number of circuits including the spinal cord, the reticulospinal tract, the basal ganglia, and the primary motor tracts.[1] In addition, as the endotracheal tube is perceived as more noxious and motor tone has returned, the patient may commonly exhibit defensive posturing indicated by reaching for the endotracheal tube.

These physiologic signs are often present in advance of the patient responding to any verbal commands. The patient need not respond to commands to be extubated. Tracheal extubation only requires that the patient have sufficient return of airway reflexes and motor function to ventilate and oxygenate adequately with spontaneous breathing. To meet the criteria for extubation of the trachea, a patient can be in a vegetative state as defined by the criteria used by neurologists and rehabilitation specialists to assess the brain states of patients recovering from coma (see Box 40.1).[13,14,73]

The corneal reflex typically returns before the oculocephalic reflex.[1] Return of the corneal reflex indicates return of function in the sensory nucleus of cranial nerve V and the motor nucleus of cranial nerve VII.[4] The afferent pathway in the corneal reflex is the ophthalmic branch of cranial nerve V that projects to the trigeminal (cranial nerve V) nucleus, whereas the efferent pathway arises from the facial nerve (cranial nerve VII) nucleus. The consensual response in the corneal reflex indicates bilateral return of the sensory and motor components of this pathway. The trigeminal nucleus and the motor nucleus of cranial nerve VII lie in the pons. Return of the oculocephalic reflex indicates return of activity in the oculomotor (III), trochlear (IV), and abducens (VI) cranial nerves, which control movement of the eyes.[4] The cranial nerves III and IV nerve nuclei are located in the midbrain, whereas the cranial nerve VI nerve nucleus is in the pons. Return of the oculocephalic and corneal reflexes provides indirect evidence that the nearby arousal centers in the pons, midbrain, hypothalamus, and basal forebrain, may have also recovered function.[1] The oculocephalic reflex may not return even though the patient is extubated.

BOX 40.1 Phases of Emergence From General Anesthesia and States of Coma Recovery

General Anesthesia Stable administration of anesthetic drugs Arousal not possible, unresponsive; eyes closed, with reactive pupils Analgesia, akinesia Drug-controlled blood pressure and heart rate Mechanically controlled ventilation EEG patterns ranging from delta and alpha activity to burst suppression	**Brain-Stem Death** No respiratory response to apneic oxygenation test Total loss of brain-stem reflexes Isoelectric EEG pattern **Coma** Structural brain damage to both cerebral hemispheres, with or without injuries to tegmental midbrain, rostral pons, or both Isolated bilateral injuries to midline tegmental midbrain, rostral pons, or both Arousal not possible, unresponsive Functionally intact brain stem, normal arterial blood gases EEG pattern of low-amplitude delta activity and intermittent bursts of theta and alpha activity or possibly burst suppression
Emergence, Phase 1 Cessation of anesthetic drugs Reversal of peripheral-muscle relaxation (akinesis) Transition from apnea to irregular breathing to regular breathing Increased alpha and beta activity on EEG	**Vegetative State** Spontaneous cycling of eye opening and closing Grimacing and nonpurposeful movements EEG pattern of high-amplitude delta and theta activity Absence of EEG features of sleep Usually able to ventilate without mechanical support
Emergence, Phase 2 Increased heart rate and blood pressure Return of autonomic responsiveness Responsiveness to painful stimulation Salivation (CN VII and IX nuclei) Tearing (CN VII nuclei) Grimacing (CN V and VII nuclei) Swallowing, gagging, coughing (CN IX and X nuclei) Return of muscle tone (spinal cord, reticulospinal tract, basal ganglia, and primary motor tracts) Defensive posturing Further increase in alpha and beta activity on EEG Extubation possible	
Emergence, Phase 3 Eye opening Responses to some oral commands Awake patterns on EEG Extubation possible	**Minimally Conscious State** Purposeful guarding movements, eye tracking Inconsistent communication, verbalizations Following oral commands Return of sleep–wake cycles Recovery of some EEG features of normal sleep–wake architecture

General anesthesia is a drug-induced, reversible coma. The physiological signs observed in the phases of emergence from general anesthesia can be related to changes in activity in specific brainstem nuclei. Emergence from general anesthesia has similarities and differences with recovery from coma due to a brain injury.

CN, Cranial nerve; *EEG*, electroencephalogram.

From Brown EN, Lydic R, Schiff ND. General anesthesia, sleep, and coma. N Engl J Med. 2010;363:2638–2650.

Patients commonly leave the operating room without return of this reflex, suggesting persistent sedation of the brainstem arousal centers. The pupils can remain pinpoint if the patient has received a substantial dose of an opioid. The pupillary light reflex can remain intact even when the patient is profoundly unconscious under general anesthesia[4]; therefore, the presence of the pupillary light reflex might not indicate a change in the level of consciousness while under general anesthesia.

Responding correctly to verbal commands, a criterion that is commonly used to assess the extent to which a patient has recovered from general anesthesia, and hence the patient's readiness for extubation, suggests a return of integrated function between the brainstem, the thalamus and cortex, and among cortical regions.[1,74,75] Responding correctly to verbal commands means that the patient is correctly interpreting auditory information and that the cranial nerve VIII nuclei located in the pons and the auditory pathways from the pons to the cortex and the relevant effector pathways have regained substantial function. If the patient inconsistently follows motor commands, then he or she is classified as being in a minimally conscious state by the criteria neurologists use in examining patients recovering from coma (see Box 40.1).[13,14,73] With emergence, the physiologic signs and neurologic findings can be related to changes in activity in specific brainstem centers. Although the EEG shows the resumption of high-frequency activity consistent with the return of cognitive processing, normal brainstem-cortical, brainstem-thalamic, thalamocortical, and intracortical communication must clearly return for full return of consciousness.[44,75-78] Current clinical monitoring approaches do not allow us to monitor these changes adequately.

Opening of the eyes is typically one of the last physiologic signs observed in patients emerging from general anesthesia. In particular, patients may respond reliably to verbal commands, have substantial return of motor functions, yet not necessarily open their eyes.[1] In general, patients tend to keep their eyes closed even when consciousness has returned. In contrast, during coma recovery, patients can have their eyes open in a vegetative state (see Box 40.1).

Emerging Strategies for Monitoring the Brain States of General Anesthesia and Sedation

In the last several years, there has been strong growth in research on the neuroscience of general anesthesia. As a result, there are several reports of new approaches to monitoring the brain states under general anesthesia.

UNPROCESSED ELECTROENCEPHALOGRAM AND THE SPECTROGRAM

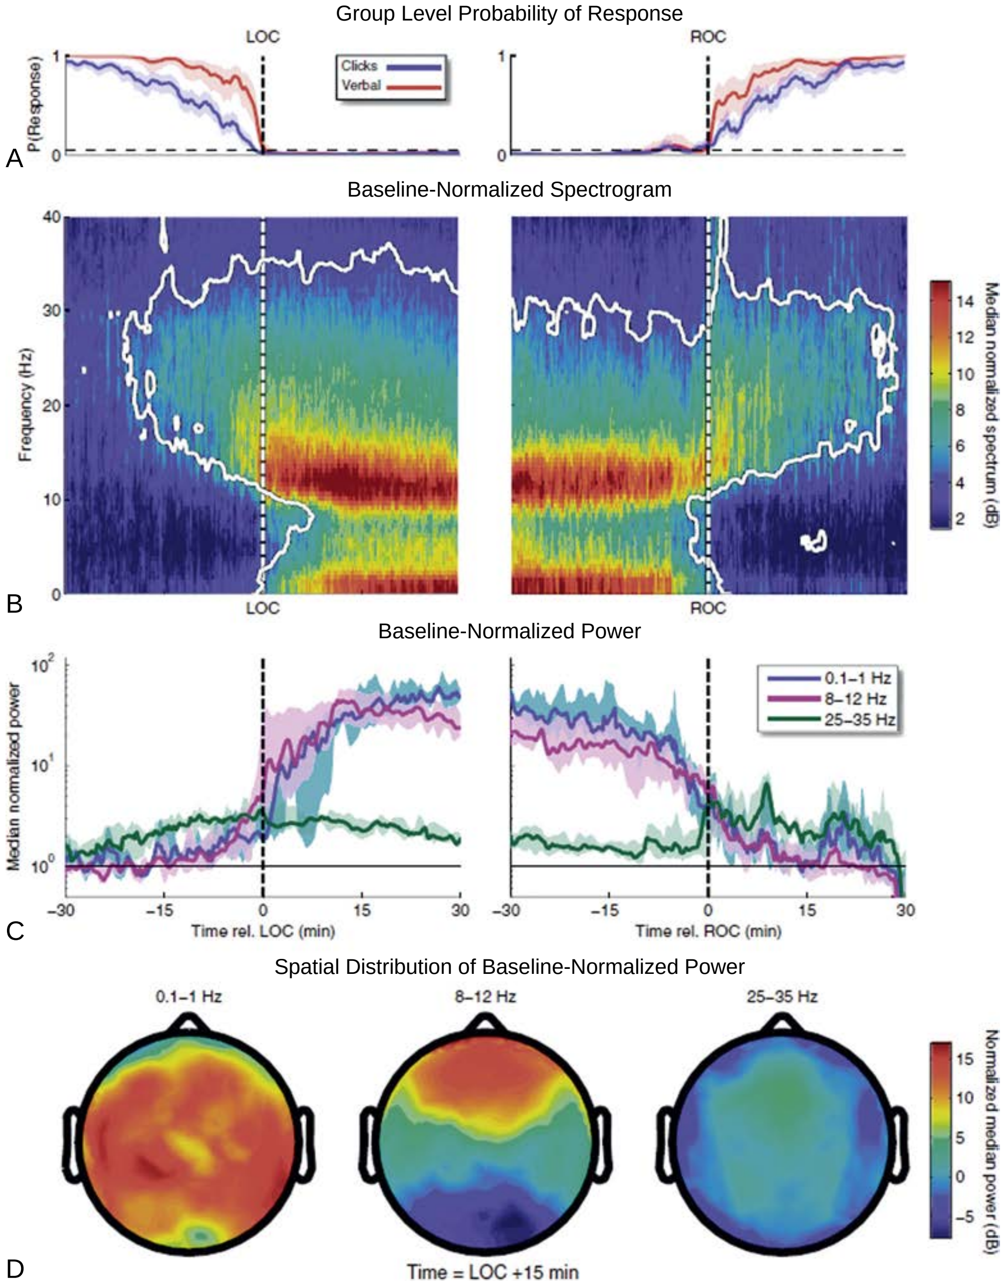
Different anesthetics have different receptor targets[79] and neural circuit mechanisms of action.[1,43] These differences in targets and neural circuits translate into different patterns of activity in the brain that are readily visible in the unprocessed EEG or its spectrogram.[26] The spectrum of a segment of EEG is the decomposition of the EEG signal into its power content by frequency.[26] Power is typically expressed in decibels which is 10 times the base 10 logarithm of the square of the amplitude of a given frequency component.[26] When the spectrum is computed on successive nonoverlapping or overlapping segments of EEG data, it is termed the *spectrogram*[26]; it is called the *compressed spectral array* when the spectrogram is plotted in three dimensions[80] and the *density spectral array* when it is plotted in two dimensions.[81]

The EEG patterns of propofol have been related to its neural circuit mechanisms. The brain states under propofol are readily visible in the unprocessed EEG and the spectrogram (see Figs. 40.2, 40.6 and 40.7, *A*). Propofol acts primarily at $GABA_A$ receptors throughout the brain and spinal cord to enhance inhibition in neural circuits.[79,82] When patients are unconscious from propofol, the EEG shows a characteristic alpha (8-12 Hz) oscillation pattern along with slow (0.1-1 Hz) and delta (1-4 Hz) oscillation patterns (see Fig. 40.7 *A*).[44,49,83,84] Another phenomenon that is observed in patients who are unconscious from propofol and several other anesthetics is anteriorization—the increase in power in the alpha and beta frequency ranges during unconsciousness across the front of the scalp relative to other areas of the scalp (see Fig. 40.6, *C* and *D*).[44,47,49]

During unconsciousness, the alpha oscillations are highly coherent across the front of the scalp, whereas the slow and gamma oscillations are not coherent.[44,49,84] Highly coherent alpha oscillations have also been identified in animal studies of inhaled anesthetics during unconsciousness.[85] The coherent structure in the alpha oscillations is most likely due to strong alpha oscillations between the thalamus and frontal cortex.[86] The slow oscillations are a marker of fragmented intracortical communication because in the presence of the slow oscillations, cortical neurons spike only in a limited phase dictated by their local slow oscillations.[84] As the slow oscillations are spatially incoherent and spiking is phase limited, neuronal communication among brain regions that are separated by more than 1 cm is greatly impeded. There is a strong modulation of the alpha oscillation amplitude by the phase of the slow-delta oscillation[44]. Patients are profoundly unconscious when the maximum amplitude of the alpha oscillations occurs at the peak of the slow oscillation waveform.[44] In contrast, patients are likely to be arousable when the maximum amplitude of the alpha oscillations occurs at the trough of the slow oscillation waveform.[44] With return of consciousness, the alpha and slow oscillations dissipate (see Fig. 40.6.*B*). A mechanism by which propofol produces unconsciousness is through hypersynchronous alpha oscillations impeding communication between the thalamus and prefrontal cortex and through highly desynchronous slow oscillations impeding intracortical communication.[44,84,86,87]

Similarly, the EEG patterns of ketamine (see Fig. 40.7, *B*)[27] and dexmedetomidine (Fig. 40.8, *A* and*B*)[34] are distinctive and can be related to the mechanisms of actions of these drugs in the brain and central nervous system.[1,3,43] Ketamine acts principally by binding to *N*-methyl-D-aspartate (NMDA) receptors.[43,88] Thus, with small to moderate doses, ketamine has its primary effect by blocking excitatory glutamatergic inputs to inhibitory interneurons.[89,90] Impaired control over pyramidal neurons is why increases in cerebral metabolism, and the appearance of altered behavioral states including hallucinations, dissociative states, euphoria, and dysphoria, are common with low-dose ketamine. Brain regions, such as the limbic system, cortex, and thalamus, continue to communicate but with much less regulatory control from the inhibitory interneurons—that is, information processing proceeds in the absence of proper coordination in time and space.[1,43] Increasing the dose of ketamine blocks the NMDA receptors on the excitatory glutamatergic neurons, and eventual loss of consciousness, as when ketamine is used to induce anesthesia.[91] The increased activity of pyramidal neurons throughout the brain is consistent with the high frequency (20-30 Hz) oscillations that are commonly observed in the EEG of patients receiving ketamine (see Fig. 40.7 *B*).[27,92] This high-frequency EEG activity helps explain why EEG-based indices often give high values in patients receiving ketamine.

Dexmedetomidine induces its sedative effects primarily by actions on presynaptic α2-adrenergic receptors on neurons that project from the locus ceruleus.[93-95] Binding of dexmedetomidine results in a decrease in the release of norepinephrine from these neurons.[96-98] Loss of the norepinephrine-mediated inhibition to the preoptic area of the hypothalamus leads to activation of the preoptic area's GABAergic and galanergic inhibitory inputs to most of the principal arousal centers in the midbrain, pons, basal forebrain, and hypothalamus.[99] Activation of inhibitory inputs from the preoptic area is postulated to be a component of how nonrapid eye movement (NREM) sleep is initiated.[100,101] This suggests why light sedation with dexmedetomidine shows spindles, intermittent bursts of 9 to 15 Hz oscillations, and slow-wave patterns in the EEG that closely resemble NREM sleep stage 2 (see Fig. 40.8, *A*). Recent studies have demonstrated that deep sedation with dexmedetomidine also shows the combined spindle and slow-delta oscillation patterns seen with light dexmedetomidine sedation (see Fig. 40.8, *A*), along with an appreciable decrease in beta oscillation power.[32,33,102] Deep



Group Level Probability of Response

Baseline-Normalized Spectrogram

Baseline-Normalized Power

Spatial Distribution of Baseline-Normalized Power

Fig. 40.6 Behavioral and electroencephalogram dynamics of loss and recovery of consciousness from propofol. (A) Group-level (10 subjects) click or nonsalient stimulus *(blue, P_{clicks})* and verbal or salient stimulus *(red, P_{verbal})* response-probability curves. (B) Group-level spectrograms computed by baseline-normalization from a frontal channel (approximately *Fz*, using nearest-neighbor Laplacian reference) aligned across subject with respect to loss of consciousness *(LOC)*. Area enclosed within the white borders show where power is significantly different from baseline ($P < .05$, sign test) and shows significant power increases spanning slow (0.1-1 Hz) through gamma (25-35 Hz) bands. (C) Time course of group-level power in slow, alpha (8-12 Hz), and gamma bands aligned with respect to LOC and recovery of consciousness *(ROC)*. (D) Group-level spatial distribution of slow, alpha, and gamma power during unconsciousness (LOC + 15 min). The frontal increase in alpha power is termed *anteriorization*. These analyses illustrate that changes in broad-band gamma/beta power occur with the behavioral changes before LOC and after ROC, whereas changes in slow and alpha power occur with LOC and ROC. (From Purdon PL, Pierce ET, Mukamel EA, et al. Electroencephalogram signatures of loss and recovery of consciousness from propofol. *Proc Natl Acad Sci U S A.* 2013;110:E1142–E1151.)

sedation with dexmedetomidine can also show a slow-delta oscillation EEG pattern that closely resembles the patterns observed in NREM sleep stage 3 or slow-wave sleep (see Fig. 40.8 *B*).[26]

Sevoflurane, like the other inhaled ether anesthetics, produces its physiologic and behavioral effects by binding at multiple targets in the brain and spinal cord. These include binding to $GABA_A$ receptors and enhancing GABAergic inhibition, and blocking glutamate release by binding to NMDA receptors, along with activating two-pore potassium channels and hyperpolarization-activated cyclic nucleotide-gated channels.[79] Although debates still exist over the relative importance of these targets, sevoflurane and the other ether anesthetics have distinct EEG signatures.

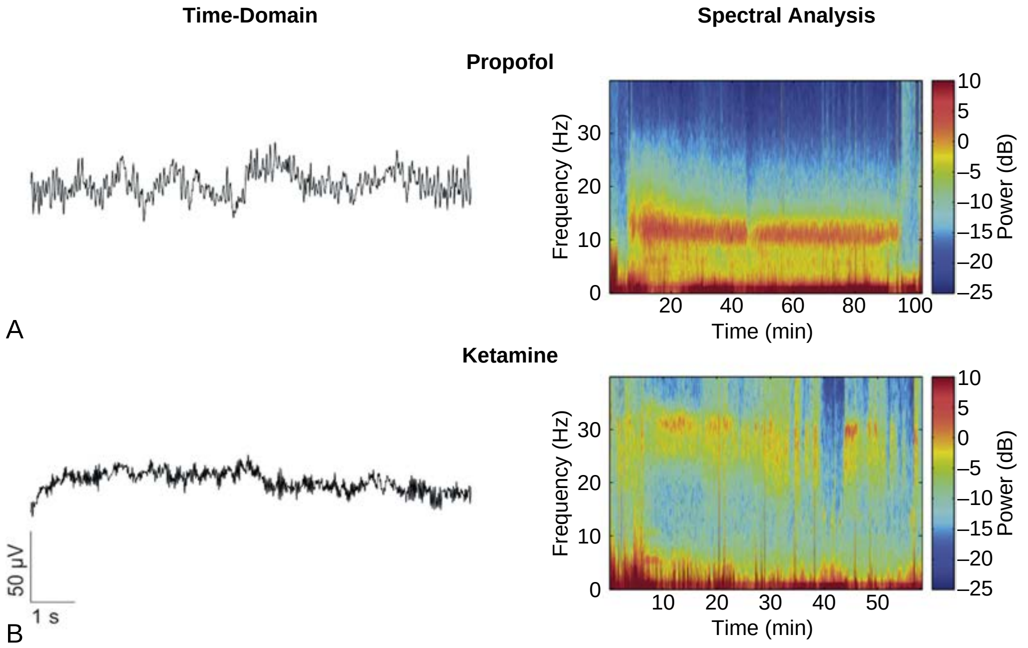


Fig. 40.7 Time-domain and spectral electroencephalogram (EEG) signatures of common anesthetics. The left column shows a 10-s time-domain (unprocessed) segment of the EEG for each anesthetic. The right column shows several minutes of the spectrogram (density spectral array) computed from the EEG for each anesthetic. (A) The EEG and spectrogram of propofol show its characteristic alpha (8-12 Hz) and slow-delta (0.1-4 Hz) oscillation pattern. (B) The ketamine EEG and spectrogram show high frequency oscillations in the high beta (20-24 Hz) and low gamma (25-35 Hz) range.

At doses of sevoflurane appropriate for general anesthesia, the EEG shows strong alpha and slow oscillations like propofol, in addition to a strong theta (4-8 Hz) oscillation (see Fig. 40.8 *C*). The presence of the theta oscillations creates a distinctive pattern of evenly distributed EEG power from the slow oscillation through the alpha oscillation range. The predominance of the alpha and slow oscillations in the sevoflurane spectrogram and those of the other inhaled ethers suggest that GABA$_A$-mediated inhibition is a primary mechanism of action of these anesthetics. This spectrogram pattern further suggests that a primary mechanism through which the inhaled ethers produce unconsciousness is largely similar to that of propofol.[44,84,86,87]

Nitrous oxide has a highly distinctive EEG dynamic. A common practice in our institution, at the end of surgery, is to switch from the inhaled ether, isoflurane, to nitrous oxide to facilitate emergence from general anesthesia (Fig. 40.9 *A*). When nitrous oxide is administered at high doses (greater than 50%), it produces large slow-delta oscillations that last from 3 to 12 minutes before converting to high-frequency gamma oscillations (see Fig. 40.9 *B*).[26,31,103,104] Why the slow-delta oscillations are transient is unknown. Nitrous oxide is known to act by blocking NMDA glutamate receptors.[31,79,105,106] It is likely that the slow-delta oscillations reflect a transient profound state of unconsciousness most likely mediated through inactivation of key NMDA glutamate projections from the parabrachial nucleus and from the median pontine reticular formation into the central thalamus and basal forebrain.[31,107]

Although the unprocessed EEG recordings of the anesthetics can look similar, the spectrograms make clear that each anesthetic has a distinct EEG signature. These signatures can be related to the mechanisms through which the drugs act at specific receptors in specific neural circuits to alter arousal. Using the spectrogram to monitor brain function under general anesthesia and sedation is fundamentally different from using EEG-based indices that are predicated on the assumption that different anesthetics can create the same anesthetic state irrespective of mechanism. The differences in the spectral signatures between propofol (see Fig. 40.7 *A*) and ketamine (see Fig. 40.7 *B*) illustrate why the latter often gives a high index reading when clinically the patient is clearly sedated. Similarly, the predominance of the slow-wave oscillations observed during deep dexmedetomidine (see Fig. 40.8, *B*) sedation helps explain why this drug gives low index values consistent with profound unconsciousness yet the patient remains arousable.

CHANGES IN ELECTROENCEPHALOGRAM SIGNATURES WITH AGING

In addition to changing systematically with anesthetic class, the EEG signatures of patients under general anesthesia change systematically with age. Fig. 40.10 shows the spectrogram of patients of different ages anesthetized with propofol. There are three principal changes in the EEG signatures of propofol with age. First, the EEG of children between 0 to 3 months of age, anesthetized with propofol or another GABAergic drug such as sevoflurane as the primary hypnotic, show only slow-delta oscillations (see Fig. 40.10, *A* and *B*).[108] Slow-delta and alpha oscillations do not appear together until children are at least 4 months of age or older (see Fig. 40.10 *C*).[108] The alpha oscillations become coherent and show anteriorization specifically at the alpha frequency, at approximately 1 year of age.[37,38,108,109] Coherence means the oscillations are highly synchronized, whereas anteriorization means that the oscillations are predominant in the

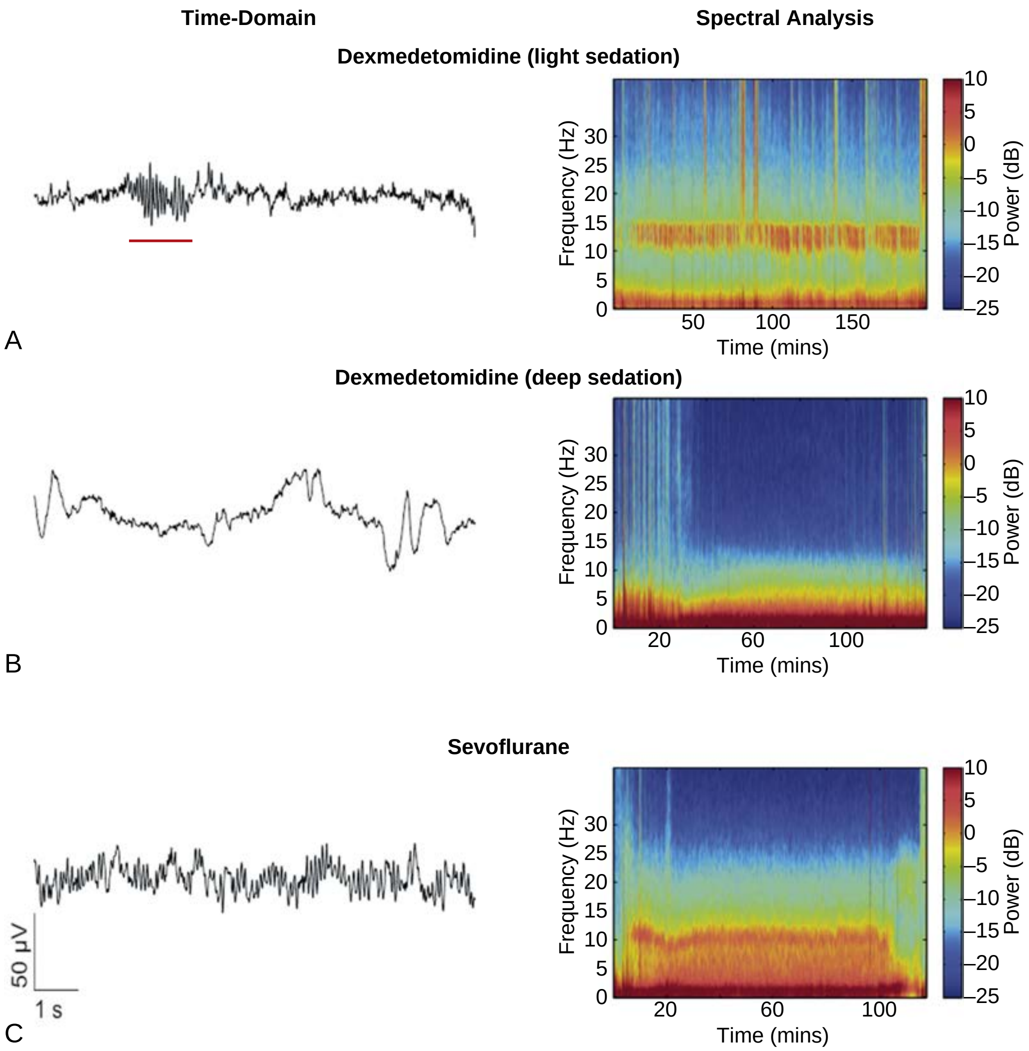

Fig. 40.8 Time-domain and spectral electroencephalogram (EEG) signatures of common anesthetics. The *left column* shows a 10-second time domain (unprocessed) segment of the EEG for each anesthetic. The *right column* shows several minutes of the spectrogram (density spectral array) computed from the EEG for each anesthetic. (A) The dexmedetomidine EEG and spectrogram for light sedation shows spindle (9-15 Hz) oscillations, and the slow (0.1-1 Hz) oscillations, and delta (1-4 Hz) oscillations similar to the EEG patterns observed in nonrapid eye movement (NREM) sleep stage 2. The spindle is apparent in the unprocessed EEG trace (red underscore). The spindles are intermittent and have less intensity than the alpha oscillations observed with propofol. (B) The EEG and spectrogram for deep dexmedetomidine sedation can be associated with an absence of spindles and a predominance of slow and delta waves similar to the slow waves seen in NREM sleep stage 3, termed *slow-wave sleep*. (C) The sevoflurane spectrogram is similar to propofol with the addition of oscillatory activity in the theta band from 4 to 8 Hz.

frontal EEG leads and completely absent in the occipital leads. The mechanisms underlying these age-dependent changes are unclear, but they almost certainly reflect development of underlying brain circuits in children.[37,38,110] According to computational modeling studies propofol can generate alpha oscillations as a result of increasing inhibition in cortical networks.[111] When thalamocortical components are added to this model, the alpha oscillations become highly coherent.[86] Hence, the development of propofol- and sevoflurane-induced alpha oscillations in the first 6 months of life could reflect developing inhibition, particularly within cortical circuits.[110] The later development of coherent alpha oscillations could reflect developing thalamocortical connections that facilitate coherent alpha oscillations.[86,112] Although not shown in the figures presented here, the total power in the spectrogram increases with age from 0 months to a maximum at approximately 6 to 8 years and then declines from there with each year of age.[37,38]

Second, the alpha band is characteristic of young adults (approximately 18-35 years of age) and ranges from 8 to 15 Hz for this group (see Fig. 40.10 *F*). The corresponding band for ages below 18 years falls generally over a broader frequency range, 10 to 20 Hz (see Fig. 40.10, *D* and*E*), and has higher power relative to the alpha band of the young adults (see Fig. 40.10 *F*). The corresponding band for ages greater than 35 years falls generally over a narrower frequency range, 6 to 10 Hz (see Fig. 40.10 *G*), and has less power relative to the alpha band of the young adults (see Fig. 40.10 *F*). Third, the alpha oscillations in adults 55 years or older may be diminished and in the lower frequency range from 6 to 10 Hz or nearly absent (see Fig. 40.10, *G-I*).

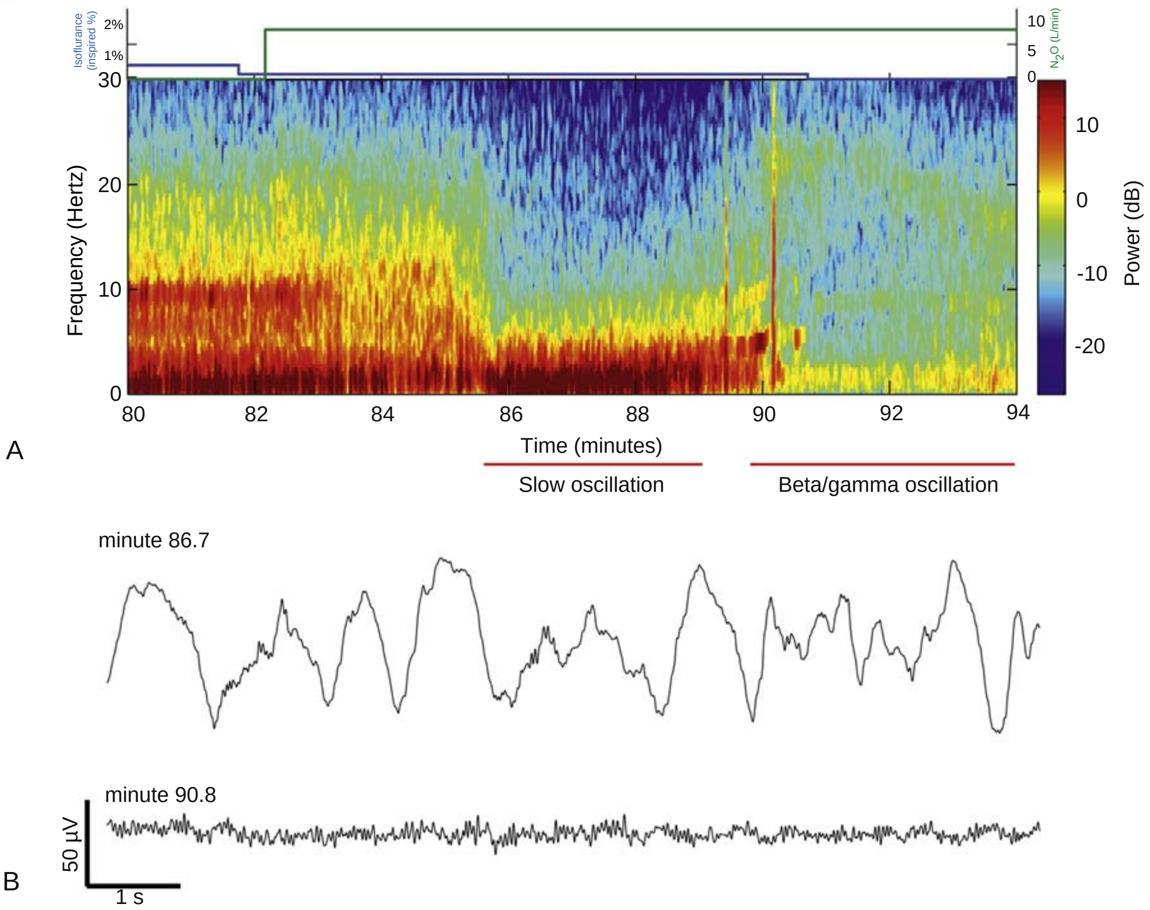

Fig. 40.9 Spectrogram displays of nitrous oxide-induced slow-delta and beta-gamma oscillations. (A) To facilitate emergence, a patient maintained on a mixture of 0.5% isoflurane and 58% oxygen at 3 L/min was changed to 75% nitrous oxide and 24% oxygen at 7 L/min. Between minutes 83 and 85 the slow-delta, theta, and alpha oscillation power decreased. The beta and theta band power appreciably decreased whereas the slow-delta oscillation power substantially increased beginning at minute 86. By minute 90 the slow-delta oscillation power has noticeably decreased, and beta-gamma oscillations begin to appear. (B) Electroencephalogram traces of the slow-delta oscillations recorded at minute 86.7 and the beta-gamma oscillations recorded at minute 90.8. Each trace is 10 s.

The changes in the slow-delta oscillations follow similar changes to the alpha oscillations band in that the band is broad with high power at younger ages (see Fig. 40.10, *C-E*) and becomes narrower with lower power with aging (see Fig. 40.10, *F-I*). Indeed, the alpha and slow-delta oscillations of the 56-year old patient and of the 81-year old patient are barely perceptible (see Fig. 40.10).

Fig. 40.10, *F-G* show that there can be significant between-person variation in power for patients of approximately the same age. The 57-year-old patient (see Fig. 40.10 *G*) has alpha and slow-delta oscillations that resemble the pattern seen in the 30-year-old patient (see Fig. 40.10 *F*), whereas the alpha and slow-delta oscillations of the 56-year-old patient (see Fig. 40.10 *H*) resemble those of the 81-year-old patient (see Fig. 40.10 *I*). We conjecture that these differences in oscillatory dynamics induced by propofol reflect between - individual variation in normal brain aging.[113] The age-related EEG changes of sevoflurane, and presumably those associated with isoflurane and desflurane, are similar to those of propofol, given that all of these agents have primary GABAergic mechanisms of action.

IMPLICATIONS FOR MONITORING ANESTHETIC STATE

These observations suggest that the unprocessed EEG and the spectrogram can be used to monitor the brain states of patients receiving anesthesia care (see Figs. 40.6 to 40.10). The unprocessed EEG waveform has been advocated as a tool for monitoring "depth of anesthesia" since 1937.[16,17,26,114,115] Although the spectrogram is easy to compute in real time and has been reported in studies of anesthetics,[80,81,116] a strategy to use it in conjunction with the unprocessed EEG and the EEG-based indices for management of patients receiving anesthesia care is now being developed. Many of the current EEG brain function monitors display both the unprocessed EEG and the spectrogram.[22,54,117] Training anesthesia providers to track brain states under general anesthesia and sedation by reading the unprocessed EEG and the spectrogram is a program being pursued currently in the Department of Anesthesia, Critical Care and Pain Medicine, of Massachusetts General Hospital in collaboration with the International Anesthesia Research Society (www.eegforanesthesia.iars.org).

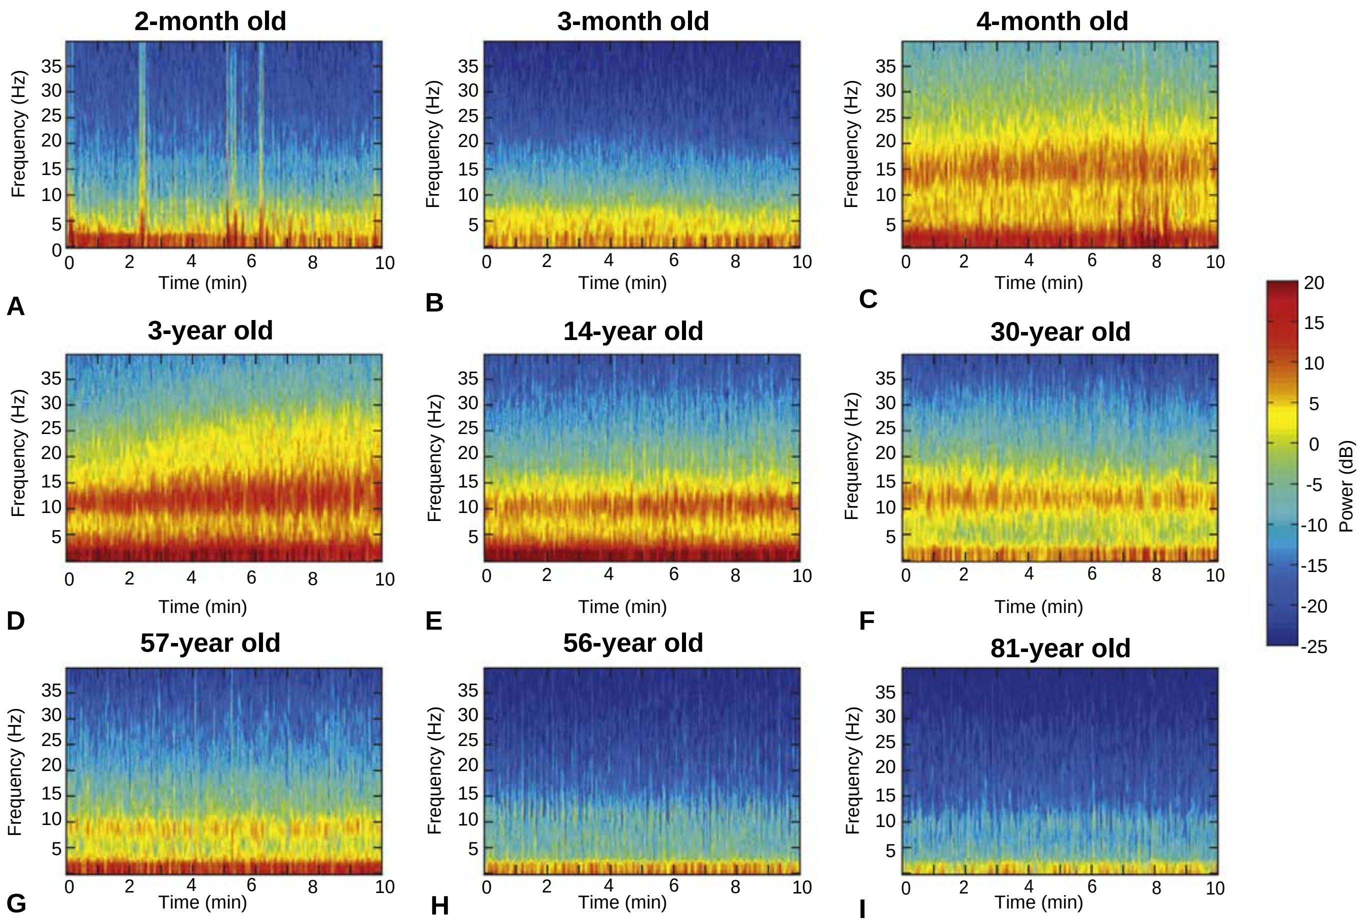

Fig. 40.10 Spectral electroencephalogram signatures of propofol as a function of age. Each panel is a 10-minute segment recorded from a patient receiving a propofol infusion as the primary anesthetic to maintain unconsciousness. The spectral power in all of the panels are plotted on the same decibel scale. (A) A 2-month-old patient. (B) A 3-month-old patient. (C) A 4-month-old patient. (D) A 3-year-old patient. (E) A 14-year-old patient. (F) A 30-year-old patient. (G) A 57-year-old patient. (H) A 56-year-old patient. (I) An 81-year-old patient. Children less than 4 months of age show only slow-delta oscillations. Alpha oscillations appear at 4 months of age. Although children greater than 4 months of age and adults from 18 to 55 years of age show both slow-delta and alpha oscillation patterns under propofol, the frequency range of the alpha oscillations and the power content changes with age. Elderly patients often have a noticeable decrease in or absence of alpha oscillations.

Another EEG education resource has been developed at Washington University (icetap.org). Highly structured oscillations are the sine qua non of anesthetic states. Therefore, use of the spectrogram to track level of consciousness under general anesthesia and sedation facilitates direct integration of clinical and research observations from EEG recordings with experimental studies and biophysically-based modeling studies that help define the neural circuit mechanisms of anesthetic actions.[86,111,118,119]

NORMALIZED SYMBOLIC TRANSFER ENTROPY

A growing body of information suggests that a key marker or mechanism of unconsciousness under general anesthesia is loss of intracortical connectivity.[74,75,84,91,120,121] The loss of functional connectivity between the frontal and parietal areas is associated with unconsciousness.[91,120] By using the EEG recorded from a montage that includes both frontal and parietal electrodes, a mutual information technique termed normalized symbolic transfer entropy (NSTE) can be used to measure this loss of functional connectivity (Fig. 40.11). When NSTE is used to assess functional connectivity from the parietal area to the frontal cortical area, it is termed *feedforward functional connectivity*, whereas when it is used to assess functional connectivity from the frontal area to the parietal area, it is termed *feedback functional connectivity*.

Unconsciousness induced by propofol, sevoflurane, or ketamine has been associated with loss of feedback functional connectivity (see Fig. 40.11).[91,120] As a consequence, measuring NSTE to assess functional connectivity could provide a means of monitoring the level of consciousness in patients receiving general anesthesia. The loss of feedback functional connectivity is present for unconsciousness induced by all three anesthetics, suggesting that NSTE does not distinguish among the mechanisms of actions of these anesthetics.[120] Nevertheless, NSTE could still offer a way to track levels of unconsciousness.

A partial answer regarding the mechanism of loss of the feedback functional connectivity for unconsciousness induced by propofol and the inhaled ether anesthetics may be related to anteriorization (see Fig. 40.6, *D*). The model by Vijayan and colleagues[119] shows that anteriorization can be explained by the differences in the electrophysiologic

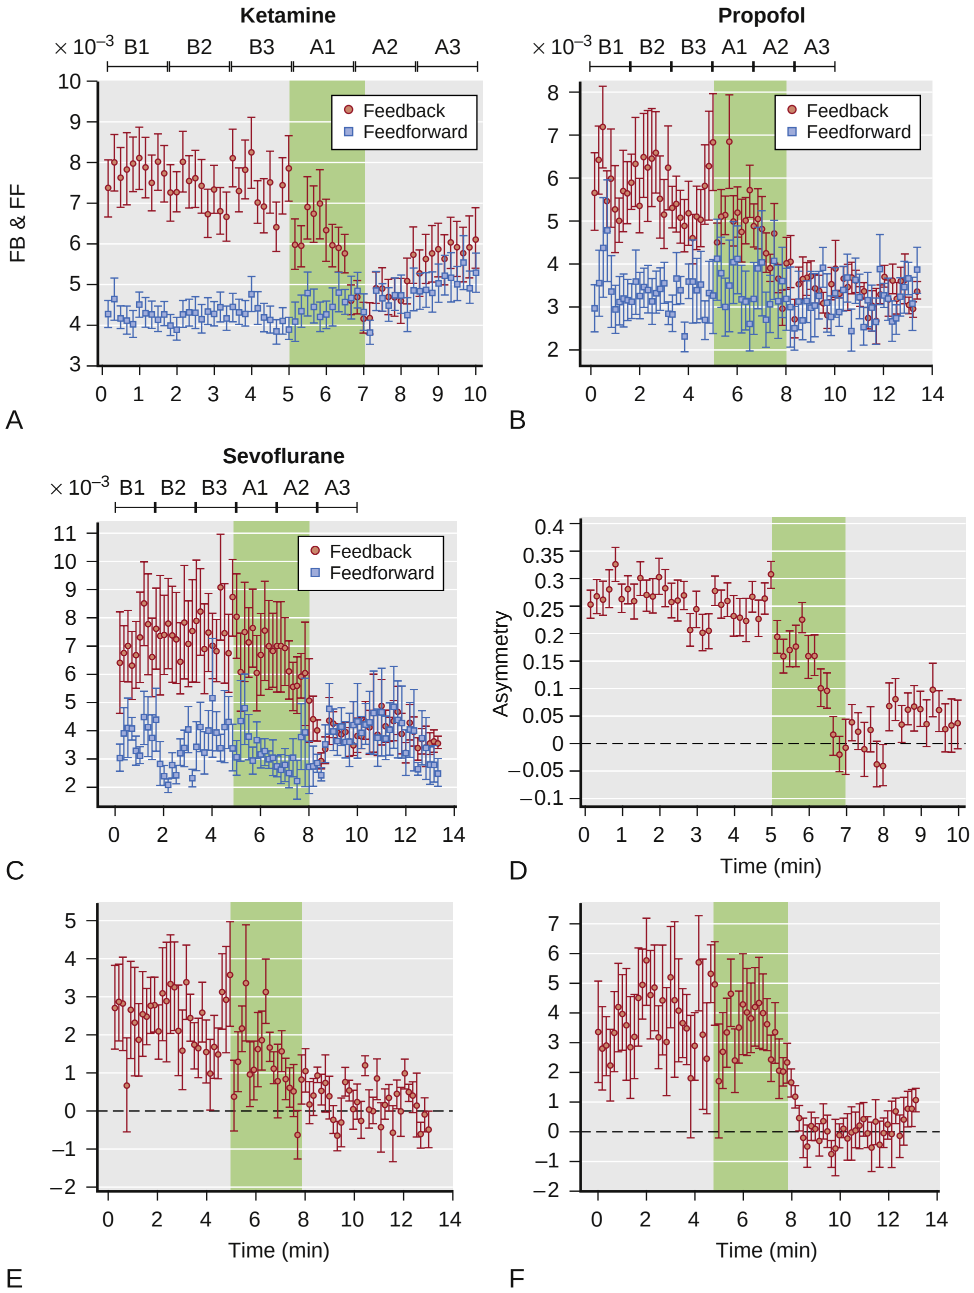

Fig. 40.11 Normalized symbolic transfer entropy. An analysis of loss of consciousness induced by ketamine, propofol, and sevoflurane using normalized symbolic transfer entropy. Asymmetry in the change of feedforward *(FF)* and feedback *(FB)* connectivity is common to all three anesthetics. The FF *(blue)*/FB *(red)* connections (A–C) and their associated asymmetry (D–F) in the frontal–parietal network displayed for (A and D) ketamine, (B and E) propofol, and (C and F) sevoflurane. Green shading highlights induction of general anesthesia. *B1 to B3* define baseline substates. *A1 to A3* define anesthetized substates. There were 30, 9, and 9 subjects in the ketamine, propofol, and sevoflurane groups, respectively. All three anesthetics show a greater loss in FB frontal-parietal connectivity than FF connectivity at loss of consciousness. (Redrawn from Lee U, Ku S, Noh G, et al. Disruption of frontal-parietal communication by ketamine, propofol, and sevoflurane. *Anesthesiology* 2013;118:1264–1275.)

properties, such as the resting membrane potentials and ionic currents, in the frontal thalamocortical connections compared with the posterior thalamocortical connections. If the parietal circuits resemble their nearby occipital counterparts neurophysiologically, then the neurophysiologic dynamics that lead to anteriorization could also contribute to loss of feedback functional connectivity. Studies of functional connectivity changes during loss of consciousness due to general anesthesia using the Vijayan model may shed mechanistic light on the differences between changes in feedback connectivity and feedforward connectivity.

At present, the use of NSTE in the operating room is not tractable because it is not possible to compute these mutual information measures in real time.[91] Moreover, the use of NSTE in its current form requires an EEG montage with both frontal and parietal electrodes, unlike the montages used with most current brain function monitors, which require only frontal electrodes.

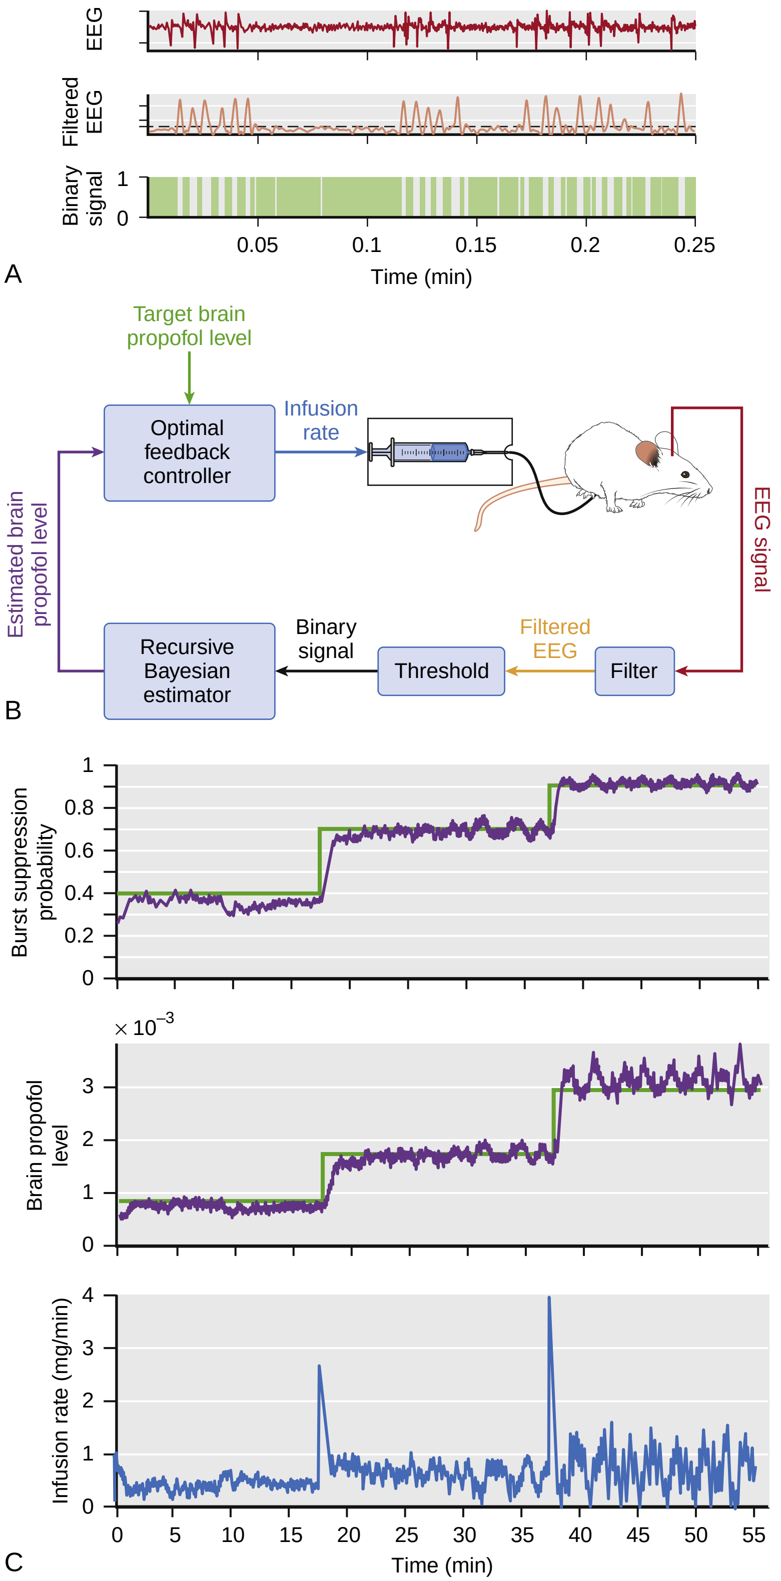

Fig. 40.12 An experimental closed loop anesthetic delivery system for control of medical coma by controlling burst suppression. (A) The electroencephalogram *(EEG)* of the rat in burst suppression is filtered, thresholded, and converted into binary observations (i.e., 0 for a burst and 1 for a suppression). (B) A target brain level of propofol is set by specifying a burst suppression probability. The Bayesian algorithm estimates the brain level of propofol from the EEG. The controller compares the estimated propofol level with the target level and adjusts the infusion rate every second to maintain the specified target burst suppression probability or, equivalently, the target brain propofol level. (C) The *top panel* shows that the target burst suppression probability *(green line)* was maintained at 0.4 for 20 minutes, changed to 0.7 for 20 minutes, and then changed to 0.9 for 15 minutes. The estimated burst suppression probability *(purple curve)* tracks exactly the targeted level. The *middle panel* shows the equivalent close tracking of the target brain propofol level *(green line)* by the estimated propofol level *(purple curve)*. The *bottom panel* shows how the controller instantaneously changed the infusion rate to maintain the targeted level of burst suppression. This experimental study establishes the feasibility of real-time control of burst suppression and most likely other states of general anesthesia. (Redrawn from Shanechi M, Chemali JJ, Liberman M, et al. A brain-machine interface for control of medically-induced coma. *PLoS Comput Biol.* 2013;9:e1003284.)

CLOSED-LOOP ANESTHETIC DELIVERY SYSTEMS

Closed-loop anesthetic delivery (CLAD) systems for maintenance of general anesthesia and sedation have been proposed since the early 1950s. These studies have been summarized.[122,123] The CLAD systems work by using an EEG marker of anesthetic state to define a desired state for maintenance during surgery. The EEG is monitored, the marker is computed from the EEG, and a computer-controlled infusion delivering the anesthetic drug is automatically changed based on the difference between the targeted level of the EEG marker and the actual level of the marker computed from the EEG analysis. Although numerous EEG markers have been used to guide delivery of anesthetics in CLAD systems, the most widely used marker is the BIS index.[25,124] Use of the BIS requires a 20- to 30-second delay in computing updates.[24] Use of a CLAD system leads to maintenance of the desired anesthetic state while delivering significantly less anesthetic drug.[25,125-127] Although most CLAD systems have focused on maintenance of unconsciousness, a recently developed control system has studied maintenance of unconsciousness and antinociception.[128,129]

Recent simulation studies using rodent and human models, as well as recent experimental studies in rodents, have shown that highly reliable and accurate CLAD systems can be devised to maintain medical coma by using burst suppression (see Fig. 40.2 *F*) as the control variable.[122,123] A CLAD system developed by Shanechi and colleagues[130] uses a stochastic control framework and, as the control variable, the burst suppression probability, which is the instantaneous probability that the brain is suppressed (Fig. 40.12).[110] The burst suppression probability is a more reliable way to track burst suppression than the suppression ratio. The CLAD system precisely tracked the target level of burst suppression. If these results are successfully reproduced in human studies, the CLAD system could offer an automatic and highly efficient way to maintain medical coma in the many patients who require this therapy for multiple days to treat intractable status epilepticus or intracranial hypertension.

Several clinical studies have recently demonstrated the feasibility of CLAD systems as a means of controlling level of unconsciousness alone, level of unconsciousness and antinociception, and level of unconsciousness and volume status.[131-133] All of these studies have been conducted outside of the United States, as the FDA has not approved any CLAD system for administering general anesthesia. Many new findings and approaches will probably be reported in the near future because the study of CLAD systems is an active area of research by many investigators.

MONITORING ANTINOCICEPTION

The discussion of monitoring brain states under general anesthesia and sedation has focused largely on monitoring level of unconsciousness. Monitoring antinociception is an important, growing area of investigation. In the introduction, we modified the definition of general anesthesia given previously by Brown and colleagues[1] by substituting antinociception for analgesia.[3] We did so to make a precise distinction between the concept of nociception, which is transmission of potentially harmful and noxious stimuli through the sensory system, and pain, which is conscious processing of nociceptive information. When a patient is unconscious under general anesthesia, the anesthesia care provider is managing nociception, whereas when the patient is awake at the end of surgery, the care provider is managing pain. Antinociception is therefore the extent to which anesthetic and analgesic agents impede the flow of information regarding harmful and noxious stimuli through the nervous system.

At present, movement and the physiological responses of changes in heart rate, blood pressure, and perhaps respiratory rate, are the most commonly used markers of nociception. The changes in these physiological markers are a consequence of the NMA circuit responses to nociceptive information transmission in the central nervous system (see Fig. 40.1). Investigations are using multiple physiologic parameters including heart rate, heart rate variability (0.15-0.4 Hz band power), plethysmograph wave amplitude, skin conductance, skin conductance fluctuations, and the derivatives of these signals to track antinociception.[134,135] In addition, nociception can be tracked by using infrared pupillometry to record pupillary activity.[136] Commercial monitors that track level of antinociception by monitoring physiologic variables are now commercially available.[137-140] A recent report suggests that monitoring simultaneously unconsciousness and antinociception together allows the implementation of more principled multimodal strategies for choosing and administering anesthetic combinations.[3] This new strategy offers the potential to achieve better nociceptive control intraoperatively and pain control postoperatively, and to reduce the likelihood of postoperative cognitive dysfunction and opioid overuse.

41 Respiratory Monitoring

DAVID W. KACZKA, HOVIG V. CHITILIAN, and MARCOS F. VIDAL MELO

KEY POINTS

- Intraoperative respiratory monitoring is a fundamental component of the American Society of Anesthesiologists' standards for basic anesthetic monitoring. Monitoring of oxygenation and ventilation is essential for the safe conduct of an anesthetic.
- A thorough understanding of the physiological and technological principles underlying respiratory monitoring is essential for its appropriate clinical application.
- The majority of respiratory monitors in clinical use provide information at the systemic and whole-lung level from which inferences are made regarding the regional lung and tissue-level conditions.
- The degree of invasiveness of utilized monitors should be determined by clinical requirements.
- Pulse oximetry is a noninvasive, reliable, and simple method for continuously monitoring the fractional arterial oxygen saturation.
- Ventilation-perfusion mismatch, shunt, and hypoventilation are the most common causes of hypoxemia in the perioperative period. Monitoring of gas exchange, and its response to various interventions, may differentiate etiologies for hypoxemia.
- Mixed venous oxygen saturation ($S\bar{v}O_2$) allows for monitoring of the global balance between oxygen delivery and consumption. Its measurement provides information on gas exchange, cardiac output, and global oxygen consumption.
- Systems utilizing near infrared spectroscopy are used clinically to monitor regional tissue oxygenation, particularly in the brain. The value of regional tissue oxygenation monitoring for clinical management is currently being established.
- Capnography is the primary quantitative method to assess ventilation in the perioperative period. Besides providing physiologic information on ventilation, pulmonary blood flow, and aerobic metabolism, capnography is important for verifying the endotracheal tube positioning, and determining the integrity of the breathing circuit.
- End-tidal carbon dioxide (CO_2) is not always a reliable approximation of arterial CO_2 tension, especially in the presence of significant heterogeneity in the distribution of ventilation and perfusion.
- Measurement of the pressures, flows, and volumes associated with ventilation is necessary to optimize mechanical ventilation, as well as to detect pathophysiologic mechanical derangements of the respiratory system (i.e., increased airway resistance or reduced lung compliance).
- Imaging techniques have emerged as important tools for respiratory monitoring. Lung ultrasonography is increasingly utilized in emergency and perioperative settings, allowing for prompt bedside assessments of pulmonary abnormalities such as pneumothorax, lung edema, consolidation, and pleural effusions. Electrical impedance tomography is another noninvasive imaging technique that provides information on lung aeration and recruitment.
- Current approaches to respiratory monitoring primarily assess pulmonary mechanical and global gas exchange processes. The monitoring of tissue and subcellular respiration remains a desirable goal for future innovation.

Overview of Respiratory Monitoring

Respiratory monitoring is essential to every anesthetic. Its major relevance for maintenance of homeostasis and patient safety is acknowledged by its mandatory position in national and international standards for anesthetic monitoring.[1,2] Through the decades, advances in respiratory monitoring have resulted in substantial reduction in anesthetic morbidity and mortality, and opened a new era of safe anesthetic practice.[3]

Respiration is the transport of oxygen (O_2) from the environment to the body cells and the transport of carbon dioxide (CO_2) from those cells to the environment. The concept includes a component of cellular respiration, the process by which cells obtain energy in the form of adenosine triphosphate from the controlled reaction of hydrogen with O_2 to form water.[4] Thus, in its broadest sense, respiratory monitoring refers to the continuous or periodic assessment of processes involved with the exchange of respiratory gases between the environment and the subcellular pathways where those gases are utilized and produced (Fig. 41.1).[4]

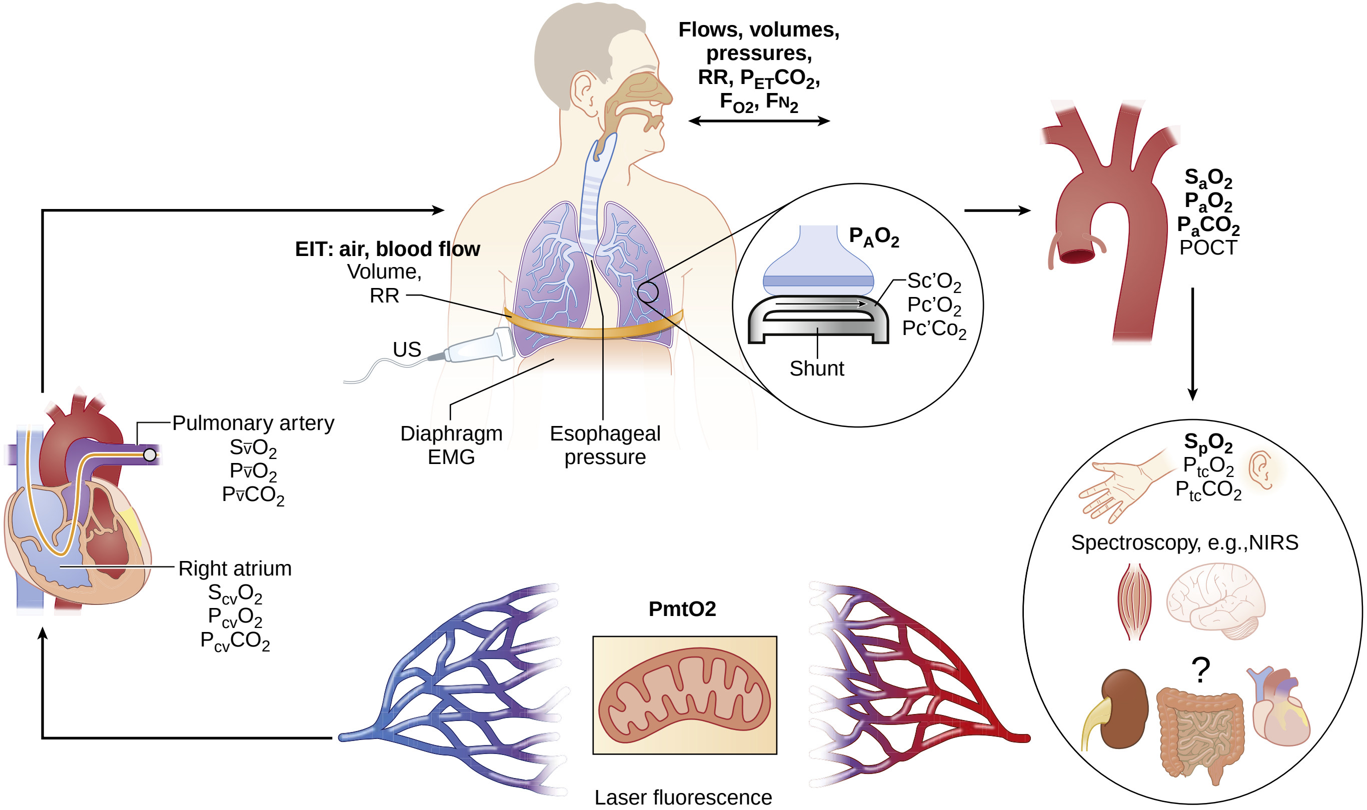

Fig. 41.1 Respiratory Processes and Measurement Sites for Current Respiratory Monitoring Techniques. Most monitored variables are derived from sites at the entrance of the airway and systemic blood (bold) and assess the elements of respiration related to global pulmonary mechanics and gas exchange. Pulse oximetry represents a transition between systemic and local tissue oxygenation assessment. Methods for routine and reliable clinical monitoring of respiratory processes at the tissue, cellular, and subcellular levels are limited. *EMG,* Electromyography; *EIT*, electrical impedance tomography; FN_2, nitrogen fraction; F_{O2}, oxygen fraction; *NIRS*, near-infrared spectroscopy; P_aCO_2, arterial partial pressure of carbon dioxide; P_aO_2, arterial partial pressure of oxygen; P_AO_2, alveolar partial pressure of oxygen; $Pc'Co_2$, end-capillary partial pressure of carbon dioxide; $Pc'O_2$, end-capillary partial pressure of oxygen; $P_{CV}CO_2$, central venous partial pressure of carbon dioxide; $P_{CV}O_2$, central venous partial pressure of oxygen; $P_{ET}CO_2$, end-tidal partial pressure of carbon dioxide;   , mixed venous partial pressure of carbon dioxide; , mixed venous partial pressure of oxygen; *POCT,* point of care testing; $P_{tc}Co_2$, transcutaneous partial pressure of carbon dioxide; $P_{tc}O_2$, transcutaneous partial pressure of oxygen; *RR,* respiratory rate; S_aO_2, arterial oxygen saturation; $S_c'O_2$, end-capillary oxygen saturation; $S_{CV}O_2$, central venous oxygen saturation; $S\bar{v}O_2$, mixed venous oxygen saturation; S_pO_2, peripheral oxygen saturation; *US,* ultrasound.

Respiratory monitoring includes assessment of (1) convective and diffusive gas transport through the branching airway tree and alveoli, (2) equilibration of gases between alveoli and pulmonary capillary blood, (3) mass balance of the distinct regional ventilation and perfusion contributions to produce expired gases and arterial and mixed venous blood, (4) gas transport between the blood and body tissues through the microcirculation, (5) gas diffusion between tissues and mitochondria, and (6) cellular respiration with O_2 use and CO_2 production.

Advances in physiologic measurements have enhanced our understanding of these stages of respiratory function during anesthesia. This chapter provides an overview of current and emerging techniques of respiratory monitoring. Despite these technical advancements, current instrumentation is limited in providing accurate and comprehensive information on respiratory function in anesthetized and critically ill patients. The area is therefore rich for research to advance the monitoring of all components of respiration.[5,6]

AMERICAN SOCIETY OF ANESTHESIOLOGISTS STANDARDS

The word *monitoring* is often associated with electronic instrumentation, and it is noteworthy that the current American Society of Anesthesiologists' (ASA) Standards for Basic Anesthetic Monitoring states in Standard I that "Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care" (Box 41.1). This precedes reliance on any instrumentation (as implied in Standard II), and clearly indicates that the anesthesia provider brings essential expertise and interpretation to monitoring beyond information provided by equipment. Increased safety in our specialty lies primarily in high-quality training and environments that encourage continuing education, and not exclusively on new technology.[7] The ASA Standards for Basic Anesthetic Monitoring reflect monitoring principles during anesthesia established in the 1980s[3] and should be systematically followed. The

BOX 41.1 American Society of Anesthesiologists Standards for Basic Anesthetic Monitoring Related to Respiratory Monitoring

Standard I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.

Standard II

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually[†] evaluated.

Oxygenation

Objective: To ensure adequate oxygen concentration in the inspired gas and the blood during all anesthetics.

Methods

Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.[*]

Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry will be employed.[*] When the pulse oximeter is utilized, the variable pitch pulse tone and the low threshold alarm will be audible to the anesthesiologist or the anesthesia care team personnel.[*] Adequate illumination and exposure of the patient are necessary to assess color.[*]

Ventilation

Objective: To ensure adequate ventilation of the patient during all anesthetics.

Methods

Every patient receiving general anesthesia will have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag and auscultation of breath sounds are useful. Continual monitoring for the presence of expired carbon dioxide will be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.[*]

When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, will be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.[*] When capnography or capnometry is utilized, the end tidal CO_2 alarm will be audible to the anesthesiologist or the anesthesia care team personnel.[†]

When ventilation is controlled by a mechanical ventilator, there will be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.

During regional anesthesia (with no sedation) or local anesthesia (with no sedation), the adequacy of ventilation will be evaluated by continual observation of qualitative clinical signs. During moderate or deep sedation the adequacy of ventilation will be evaluated by continual observation of qualitative clinical signs and monitoring for the presence of exhaled carbon dioxide unless precluded or invalidated by the nature of the patient, procedure, or equipment.

[†] Note that "continual" is defined as "repeated regularly and frequently in steady rapid succession" whereas "continuous" means "prolonged without any interruption at any time."

[*] Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

standards represent a foundation to additional monitoring according to clinical requirements.

The Physical Examination

Physical examination remains an essential component of perioperative respiratory monitoring. It provides essential information for diagnosis and treatment, and may be the first indication of changes in patient status requiring intervention. Physical examination has limitations, but it routinely allows for detection of information relevant for the management of the patient.

Respiratory monitoring starts with inspection of the patient, either awake or during anesthesia. In elective cases, the anesthesiologist will have time to investigate causes for abnormal presentations. In emergent situations, careful inspection may be the only source of information for timely and accurate anesthetic management. The observation of respiratory distress should prompt immediate search for specific causes. Assessment of the respiratory rate provides a measure of the breathing pattern. For example, during sepsis, respiratory rate is significantly correlated with disease severity.[8] Anatomic signs relevant to respiration include (but are not limited to) deformities of the chest wall and spine, goiter, tracheostomy scar, and tracheal deviation. Functional elements to be noticed include the components of inspiration and expiration (diaphragmatic versus thoracic), duration and difficulty of inspiration and expiration, paradoxical chest wall motion, use of accessory muscles, central and peripheral cyanosis, pallor, wheezing, stridor, cough and sputum, aphonia, splinting, and clubbed fingers. Neck vein distension should be examined for a potential cardiovascular contribution to respiratory distress, noting that it is a less reliable indicator of central venous pressure during significant dyspnea. Attention should be paid to painful respiration in trauma patients, as well as the possibility of flail chest, pericardial tamponade, hemothorax, pneumothorax, pulmonary contusion, and tension pneumothorax.

Auscultation of the lung during anesthesia is another essential skill in physical diagnosis. Ambient noise, individual hearing limitations, and the acoustic properties of the stethoscope all influence the anesthesiologist's clinical judgment. A stethoscope of sufficient quality will allow for identification of distinctive normal and abnormal breath sounds: vesicular sounds, ronchi, wheezes, fine and coarse crackles, inspiratory stridor, and pleural friction. A clear understanding of the acoustic mechanisms for each of these sounds is essential for adequate clinical assessment.[9,10]

Pulse Oximetry

PHYSIOLOGIC FUNDAMENTALS

The primary role of the cardiorespiratory system is the transport of O_2 and CO_2 throughout the body. O_2 delivery is quantified as the product of arterial O_2 content and cardiac output (see Chapter 13, "Respiratory Physiology and Pathophysiology"). Arterial O_2 content (C_aO_2, in mL of O_2 per 100 mL of blood [hemoglobin—Hb], mL/100 mL) is calculated as

$$C_aO_2 = (1.34 \times S_aO_2 \times Hb) + 0.0031 \times P_aO_2 \quad (41.1)$$

where 1.34 mL/g is the O_2 binding capacity of Hb (i.e., Hüfner constant, theoretically equal to 1.39 mL/g but experimental range between 1.31 and 1.37 mL/g because of the presence of small amounts of other Hb species[11]); S_aO_2 is the O_2 saturation of Hb in the arterial blood (percent saturation/100); Hb is the concentration of Hb in the arterial blood (g/dL); 0.0031 is the solubility of O_2 in blood (mL/100 mL/mm Hg); and P_aO_2 is the arterial partial pressure of O_2 (mm Hg). As can be inferred from Eq. (41.1), S_aO_2 and Hb are the major determinants of O_2 content in the blood and consequently O_2 delivery to the tissues.

Five species of Hb are found in adult blood: oxygenated Hb (O_2Hb), deoxygenated Hb (deO_2Hb); carboxyhemoglobin (COHb); methemoglobin (MetHb); and sulfhemoglobin (SHb). Under normal circumstances, the concentrations of COHb, MetHb, and SHb are small (1%-3% for COHb and less than 1% for MetHb and SHb). *Functional* O_2 saturation (S_aO_2) refers to the amount of O_2Hb as a fraction of the total amount of O_2Hb and deO_2Hb and is expressed as

$$\text{Functional } S_aO_2 = \frac{[O_2Hb]}{[O_2Hb] + [deO_2Hb]} \times 100\,\% \quad (41.2)$$

The O_2Hb fraction or *fractional* saturation is defined as the amount of O_2Hb as a fraction of the total amount of Hb[12]:

$$\text{Fractional } S_aO_2 = \frac{[O_2Hb]}{[O_2Hb] + [deO_2Hb] + [COHb] + [MetHb] + [SHb]} \times 100\,\% \quad (41.3)$$

S_aO_2 is a function of the P_aO_2. The relationship between the two is described by the O_2Hb dissociation curve (Fig. 41.2). As can be appreciated by inspection of the curve, the relationship is not linear. This has important consequences. First, a high S_aO_2 cannot discriminate between normoxic and hyperoxic conditions; this can be relevant when attempting to limit O_2 exposure in neonates or patients at risk for O_2 toxicity. Second, a large numeric change in P_aO_2 at the flat portion of the curve (P_aO_2 approximately above 70 mm Hg) has relatively small consequences in terms of blood O_2 content. Furthermore, changes in temperature, pH, P_aCO_2, and erythrocyte 2,3-diphosphoglycerate concentration can shift the curve such that the same S_aO_2 can be present under a range of different oxygen partial pressures (PO_2). This may be relevant, given that diffusion from the microcirculation to tissue depends on PO_2 gradients.

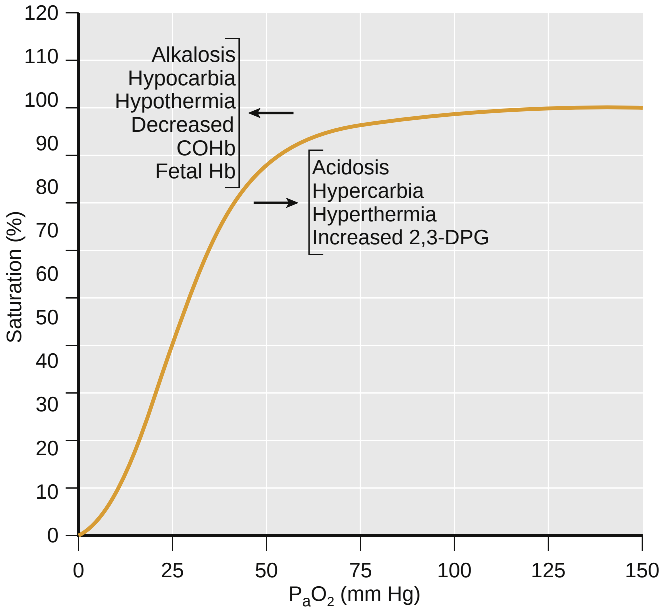

Fig. 41.2 Oxyhemoglobin Dissociation Curve. The relationship between oxyhemoglobin saturation and arterial partial pressure of oxygen is nonlinear and affected by a number of different factors such as pH, PCO_2, and temperature. Given the nonlinear nature of the curve, it is difficult to determine the partial pressure of oxygen at the higher range of oxygen saturations. *2,3-DPG,* 2,3-diphospoglycerate; *COHb*, carboxyhemoglobin. MEASUREMENT PRINCIPLES

Oximetry

Oximetry is the measurement of the O_2 saturation of Hb. It is an application of the Beer-Lambert law (Eq. 41.4), which relates the transmission of light through a solution to the concentration of the solute in the solution.[13] For each solute in a solution,

$$I_{trans} = I_{in} e^{-DC\varepsilon} \quad (41.4)$$

where I_{trans} is the intensity of transmitted light, I_{in} is the intensity of the incident light, e is the base of the natural logarithm, D is the distance the light is transmitted through the solution, C is the concentration of the solute, and ε is the extinction coefficient of the solute.

The concentration of a single solute in solution can be calculated by measuring the amount of light transmitted through the solution as long as the other variables are known. For a solution containing multiple solutes, the calculation of the concentrations of the different solutes requires that light absorption be measured at a number of different wavelengths at least equal to the number of solutes. In a sample of blood in a cuvette, the absorption of a given wavelength of light passing through the blood will depend on the concentrations of the different species of Hb. Fig. 41.3*A* illustrates the absorption spectra of the five species of Hb for wavelengths of light along the visible spectrum. To measure the concentrations of all five species of Hb in a sample of blood, light absorption of at least five different wavelengths must be measured. This measurement is typically conducted using a co-oximeter. A co-oximeter uses the principle of oximetry to measure the S_aO_2 as well as the concentrations of other Hb species in a blood sample.

Co-oximetry is considered the gold standard for S_aO_2 measurements and is relied on in circumstances when pulse oximetry readings are inaccurate or unobtainable.

Pulse Oximetry

Standard pulse oximetry aims to provide a noninvasive, in vivo, and continuous assessment of functional S_aO_2. Estimates of S_aO_2 based on pulse oximetry are denoted as S_pO_2. The history of the development of the pulse oximetry has been reviewed in detail elsewhere.[14]

Pulse oximetry takes advantage of the pulsatility of arterial blood flow to provide an estimate of S_aO_2 by differentiating light absorption by arterial blood from light absorption by other components. When compared with in vitro oximetry of an arterial blood sample, the challenge of obtaining arterial O_2 saturation in vivo is to ensure that the light is sampling arterial blood and to account for its absorption by other tissues. As illustrated in Fig. 41.4, light absorption by tissue can be divided into a time-varying (pulsatile) component, historically referred to as "AC" (from "alternating current"), and a steady (nonpulsatile) component, referred to as "DC" ("direct current"). In conventional pulse oximetry, the ratio (R) of AC and DC light absorption at two different wavelengths is calculated. The wavelengths of light are selected to maximize the difference between the ratios of the absorbances of O_2Hb and deO_2Hb (see Fig. 41.3*B*). The most commonly used wavelengths of light are 660 nm and 940 nm. At 660 nm, there is greater light absorption by deO_2Hb than by O_2Hb. At 940 nm, there is greater light absorption by O_2Hb than by deO_2Hb,

$$R = \frac{AC_{660}/DC_{660}}{AC_{940}/DC_{940}} \qquad (41.5)$$

where AC_{660}, AC_{940}, DC_{660}, and DC_{940} denote the corresponding AC and DC components of the 640-nm and 940-nm wavelengths.

The ratio R is then empirically related to O_2 saturation based on a calibration curve internal to each pulse oximeter (Fig. 41.5).[13] Each manufacturer develops its own calibration curve by having volunteers breathe hypoxic gas mixtures to create a range of S_aO_2 values between 70% and 100%. The FDA

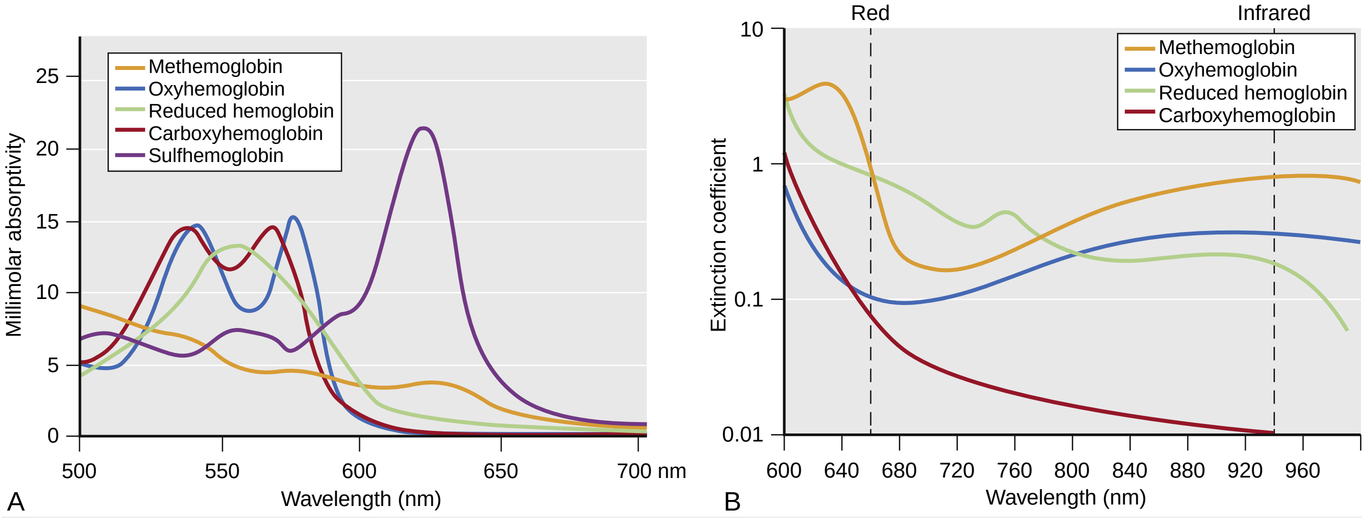

Fig. 41.3 (A) Absorption spectra of five species of hemoglobin for wavelengths of light across the visible spectrum. (B) Extinction coefficients of the most frequently measured hemoglobin species extending to infrared wavelengths used for pulse oximetry. The vertical lines indicate specific wavelengths for red and infrared light applied in pulse oximeters. The differences in the extinction coefficients of oxyhemoglobin and reduced hemoglobin (deoxygenated hemoglobin) are pronounced at these wavelengths. Note that the extinction coefficients of carboxyhemoglobin and methemoglobin are similar to those of oxyhemoglobin and reduced hemoglobin, respectively, at 660 nm. Fig. 41.4 Schematic of the Pulse Principle. Absorption of light passing through tissue is characterized by a pulsatile component (AC) and a nonpulsatile component (DC). The pulsatile component of absorption is due to arterial blood. The nonpulsatile component is due to venous blood and the remainder of the tissues. (Redrawn from Severinghaus JW. Nomenclature of oxygen saturation. *Adv Exp Med Biol*. 1994;345:921–923)

recommends root mean square differences between measured values (S_pO_2) and reference values (S_aO_2) under normal conditions ranging from 70% to 100% S_pO_2 of ≤3.0% for transmittance, wrap and clip pulse oximeter sensors and of ≤3.5% for ear clip and reflectance sensors.[14a] Most manufacturing literature reports an accuracy of ± 2% to 3% S_pO_2 over this range.[15] The dependence of S_pO_2 on pulsatility may result in inaccurate estimates of S_aO_2 when pulsatility is reduced or absent.

A pulse oximeter probe is composed of a light emitter and a photodetector. Transmission pulse oximetry involves the placement of the emitter and detector on opposite sides of the tissue being measured, usually of a finger. Reflectance pulse oximetry probes have the emitters and detector arranged on the same side. They are typically placed on the forehead. In a typical pulse oximeter, two light-emitting diodes (LEDs) are used to emit light at the two wavelengths. During operation, each LED is turned on and off in sequence. The photodetector measures transmission of light from each LED. When both LEDs are turned off, the photodetector measures ambient light and subtracts it from the signals obtained throughout the remainder of the cycle.[16]

Pulse oximetry has been an integral component of intraoperative anesthetic management since the first anesthetic monitoring standards were introduced in 1986.[3] It was adopted as a minimum monitoring standard by the ASA the same year and has subsequently been defined as a minimum standard for intraoperative monitoring by the World Federation of Societies of Anaesthesiologists and the World Health Organization (WHO).[17] The use of pulse oximetry is a part of the WHO safe surgery checklist.[18]

Multiwavelength pulse oximeters—that is, pulse oximeters with additional wavelengths of light to allow for the continuous noninvasive measurement of total hemoglobin concentration (S_pHb)[19]—as well as concentrations of MetHb and COHb utilizing up to 12 wavelengths have been developed.[20-21] S_pHb in the surgical and intensive care unit (ICU) settings has shown reasonable bias and precision when compared with laboratory measurements.[22-24] However, few of the measurements were obtained in patients with Hb concentrations within the clinically relevant range of 6 to 10 mg/dL.[25] Another limitation of S_pHb may be its absent or unreliable signal under conditions of low peripheral perfusion.[26] To date, noninvasive COHb measurements have not shown enough precision to replace laboratory measurements.[26,27] Accuracy has improved at hypoxic O_2 levels, but detecting COHb for S_aO_2 less than 87% is still unreliable.[28,29] Pulse oximetry-based MetHb measurements with a newer device are accurate, even under conditions of hypoxia.[30]

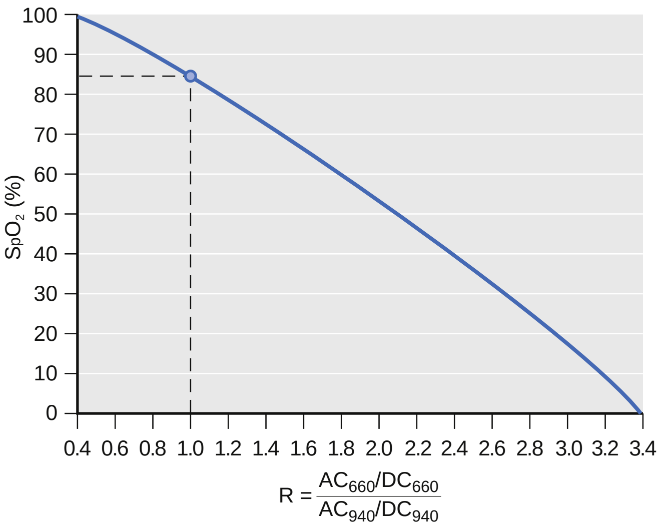

Fig. 41.5 Typical Pulse Oximeter Calibration Curve Relating Oxygen Saturation to the R Value. These curves are developed using healthy volunteers and incorporated into the pulse oximeter. *R*, Ratio of AC and DC light absorption; *S_pO_2*, peripheral oxygen saturation. [Tremper KK and Barker SJ. Pulse Oximetry. *Anesthesiology*. 1989;70:90-108.]

Universal pulse oximetry has been recommended by the US Secretary of Health and Human Services to screen newborns for critical congenital heart disease.[31,32] Use of a clinical algorithm based on detection of S_pO_2 lower than 95% in either right upper or lower limbs, or more than a 2% difference led to a sensitivity of 75% in suspected cases and 58% in cases that were not suspected. When this modality is combined with a routine anomaly scan and newborn physical examination screening, 92% of critical congenital heart disease lesions can be identified.[33,34]

Photoplethysmography. Along with measuring O_2 saturation, the pulse oximeter can also be used as a photoplethysmograph. Because the absorption of light is proportional to the amount of blood between the transmitter and photodetector, changes in the blood volume are reflected in the pulse oximeter trace (Fig. 41.6).[35] During anesthesia, the plethysmographic trace is affected by changes in blood volume pulsations, which depends on the distensibility of the vessel wall, as well as on the intravascular pulse pressure.[35] Variations in the amplitude of the pulse oximetry plethysmographic waveform (ΔPOP) have been shown to predict fluid responsiveness in mechanically ventilated patients.[36] An index derived from the percent difference between the maximum and minimum amplitudes of the plethysmographic waveform during a respiratory cycle (PVI, Pleth Variability Index) has been incorporated into a commercially available pulse oximeter and used to quantify ΔPOP and predict fluid responsiveness.[37,38] A number of studies have shown it to be a reasonably reliable indicator of fluid responsiveness perioperatively and in critically ill patients.[39,40] The technique does have greater reliability in mechanically ventilated patients compared with spontaneously breathing patients, but its accuracy may be compromised by the presence of cardiac arrhythmias.[39] Its accuracy has also been shown to be better for 500 mL fluid challenges compared with 250 mL.[41] Goal-directed fluid management based on PVI has been shown to improve outcomes in major abdominal surgery.[42]

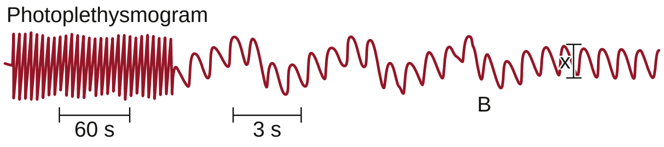

Fig. 41.6 Photoplethysmograph Recorded at Two Speeds Demonstrating Respiratory Variation. At time point (B) ventilation has been stopped, and no variation is observed. The plot illustrates the effect of intrathoracic blood volume in the pulse oximeter trace. The variation in the trace with respiration is associated with the fluid responsiveness of the patient. (Redrawn from Dorlas JC, Nijboer JA. Photo-electric plethysmography as a monitoring device in anaesthesia. Application and interpretation. *Br J Anaesth*. 1985;57:524–530.)

LIMITATIONS AND SOURCES OF ERROR

S_pO_2 is an estimate of S_aO_2 of circulating hemoglobin. As a consequence, it does not provide information about *tissue* oxygenation. Because S_pO_2 is a measurement of functional and not fractional S_aO_2, the presence of other Hb variants can significantly affect its accuracy. The nonlinearity of the Hb dissociation curve prevents the detection of hyperoxia with S_pO_2 for high S_aO_2, whereas for low saturations such as at altitude, small changes in P_aO_2 can produce large changes in S_pO_2. There is significant variability in the actual in vivo Hb dissociation curve.[43] Thus changes in S_pO_2 are not necessarily well correlated with changes in S_aO_2.[44,45] These measurements illustrate that knowledge of the individual Hb dissociation curve is important for correct interpretation of S_aO_2 and P_aO_2. More importantly, pulse oximetry does not provide information about ventilation or acid-base status.

A number of conditions can lead to inaccuracies in pulse oximeter readings (Table 41.1). These conditions include decreased perfusion, motion artifact, venous pulsation, low S_aO_2, variant Hb species, the presence of intravascular dyes, and the presence of nail polish.

Despite the recommendations of numerous boards and guidelines, there is no evidence that the use of pulse oximetry improves patient outcomes, not during transfers to ICUs nor in terms of improving patient mortality.[45a,b] There is evidence that pulse oximetry reduces the incidence of hypoxemia,[45a] and the duration and cost of ICU stay, suggesting it allows for early intervention.[45c]

The calibration of pulse oximeters is based on curves obtained in normal individuals under experimental conditions with S_aO_2 as low as 70%. As such, pulse oximeters have limited accuracy for S_aO_2 values less than 70%. Moreover, systematic errors in S_pO_2 tend to increase as S_aO_2 falls below 90%.[46] At S_aO_2 levels under 70%, a positive or negative bias of the S_pO_2 value can be observed, depending on the manufacturer of the pulse oximeter.[47] Manufacturers have developed pulse oximeters with increased accuracy at saturations as low as 60%. Preliminary data suggest that these probes may be useful in neonates with cyanotic congenital heart disease.[48]

Hypoperfusion leads to a reduction in the amplitude of the pulsatile component of the light absorbance waveform, the essential signal for pulse oximetry, consequently giving rise to absent or inaccurate readings. Significantly erroneous reductions in S_pO_2 may be observed for systolic blood pressures lower than 80 mm Hg.[49] Motion artifact can produce considerable error in the pulse oximeter reading. Manufacturers have developed advanced proprietary signal processing algorithms that effectively filter out noise caused by motion.[50,51]

With continued clinical use, the performance of the LEDs in the probe may be degraded, leading to inaccuracy in the S_pO_2 value outside of the range specified by the manufacturer. These inaccuracies are expected to be more pronounced at lower saturations (i.e., <90%).[15]

Venous pulsations may result in the detection of venous O_2Hb saturation by the pulse oximeter, resulting in artifactual reduction of the presumed arterial S_pO_2 being measured. Venous pulsations can be due to excessively tight placement of adhesive finger probes, severe tricuspid regurgitation, probe placement in dependent positions (e.g., forehead during Trendelenburg position), and possibly in distributive shock when vasodilation may result in physiologic arteriovenous shunting.[18,19,52]

TABLE 41.1 Potential Sources of Artifacts in Pulse Oximetry and Their Effects on Measurements

Source of Error	Effect on S_pO_2 Relative to S_aO_2
Hypotension	↓
Anemia	↓
Polycythemia	No significant effect
Motion	↓
Low S_aO_2	variable
Methemoglobinemia	↓/↑ (S_pO_2 approaches 85%)
Carboxyhemoglobinemia	↑
Cyanmethemoglobin	No significant effect
Sulfhemoglobin	No significant effect
Hemoglobin F	No significant effect
Hemoglobin H	No significant effect
Hemoglobin K	↓

The presence of additional species of Hb can also generate erroneous pulse oximeter readings. As outlined earlier, the function of the pulse oximeter is predicated on the assumption that the only components present in the blood capable of absorbing light at the two wavelengths used are O_2Hb and deO_2Hb. Under normal circumstances, this assumption is valid, and the S_pO_2 readings accurately reflect the S_aO_2. However, the presence of significant concentrations of other Hb species or substances absorbing light at the used wavelengths will lead to erroneous S_pO_2 readings. As illustrated in Fig. 41.3, both COHb and MetHb absorb light at one or both of the wavelengths used by the pulse oximeter. Accordingly, the presence of these Hb species will produce errors in S_pO_2. The absorption of light at 660 nm by COHb is similar to that of O_2Hb. At 940 nm, COHb absorbs virtually no light. Thus, in a patient with carbon monoxide poisoning, the S_pO_2 will be falsely elevated.[53] MetHb absorbs a significant amount of light at both 660 nm and 940 nm. As a result, in its presence, the ratio of light absorption R (Eq. 41.5) approaches unity. An R-value of 1 represents the presence of equal concentrations of O_2Hb and deO_2Hb and corresponds to an S_pO_2 of 85%. Thus, in a patient with methemoglobinemia, the S_pO_2 will be 80% to 85%, irrespective of the S_aO_2.[54] SHb absorbs red light (660 nm) more than deoxyhemoglobin (HHb) or MetHb, and likely as much near the infrared spectrum.[52] This results in S_pO_2 values close to 85% in severe cases of sulfhemoglobinemia. Although newer generations of co-oximeters can detect SHb, most existing co-oximeters cannot; consequently, additional clinical laboratory testing may be required if sulfhemoglobinemia is suspected.[52]

With normal S_aO_2, anemia has little effect on S_pO_2.[55] However, in the presence of hypoxia, S_pO_2 readings underestimate S_aO_2 in anemic patients with true hypoxemia.[56] Pulse oximeters are sufficiently accurate in adult patients with sickle cell disease,[57] as well as in the presence of fetal Hb.[58] However caution is warranted when using pulse oximetry in patients with sickle cell disease, because heme metabolism may result in elevated COHb.[52] Some studies also suggest that S_pO_2 may overestimate S_aO_2 during vaso-occlusive crises.[59,60] Another relevant point is that in patients with sickle cell disease, the affinity of O_2 for Hb is normal under normoxic conditions but becomes low during hypoxia.

A relatively uncommon cause for reduced S_pO_2 readings is the presence of congenital variants of Hb. Some variants, such as Hb Bassett, Hb Rothschild, and Hb Canabiere, have a reduced affinity for O_2, and changes in S_pO_2 appropriately reflect changes in S_aO_2.[61] Other variants, such as Hb Lansing, Hb Bonn, Hb Koln, Hb Cheverly, and Hb Hammersmith, have altered absorption spectra (closer to HHb) that result in low S_pO_2 readings in the setting of normal S_aO_2.[61]

The administration of intravenous dyes can result in inaccurate S_pO_2 readings. Methylene blue leads to a transient, marked decrease in S_pO_2 down to 65% due to its peak light absorption at 668 nm, which is very close to that of HHb. Indigo carmine and indocyanine green also artificially decrease S_pO_2 measurements, although to a lesser extent than methylene blue, because they do not substantially absorb red light.[62] Isosulfan blue can produce a prolonged reduction at higher doses.[62]

Although all colors of nail polish can reduce the calculated value of S_pO_2, black, purple, and dark blue colors have the greatest effect. Nonetheless, the error generally remains within 2%.[63] Depending on the brand of pulse oximeter, artificial acrylic nails may impair S_pO_2 readings, although generally not to a clinically significant extent.[64] Under conditions of normal S_aO_2, skin pigmentation has no effect on S_pO_2 estimates.[65] However, increased skin pigmentation is associated with S_pO_2 values that overestimate S_aO_2 by as much as 8% for S_aO_2 less than 80%.[47,66]

In the presence of severe hyperbilirubinemia (30 mg/dL or greater) caused by increased hemolysis or liver disease, the fraction of oxygenated hemoglobin (FO_2Hb) may be falsely low by artifactual increase in MetHb and COHb, resulting in more accurate S_pO_2 than FO_2Hb measurements.[52] Although earlier case reports and small studies have suggested that ambient light may interfere with the accuracy of S_pO_2 readings,[67,68] a large prospective study found no significant effect on S_pO_2 accuracy with exposure to five types of light sources: quartz-halogen, incandescent, fluorescent, infant bilirubin lamp, and infrared.[69] Infrared light pulses from image guidance systems used for navigational neurosurgery can interfere with pulse oximetry readings by causing decreased readings or disruptions in S_pO_2 waveform detection.[70] Different pulse oximeters show variable susceptibility to such interference.[71] Shielding the probe with a single layer of aluminum foil can protect from this effect.[70,71] Misplacement of the probe can allow for direct detection of LED light by the photodetector. This optical shunt gives rise to an S_pO_2 reading of 85%.[72]

In patients with intraaortic balloon pump support, S_pO_2 accuracy depends on the brand of pulse oximeter used as well as the support ratio. Accuracy is generally reduced in the setting of higher support ratios.[73] In patients with continuous flow ventricular assist devices, pulse oximetry may not be possible because of the absence of pulsatile flow. In these cases, the use of cerebral oximetry as an adjunct is advocated.[74]

Pulse Oximeter Probes

Probes are usually applied to accessible body areas with high vascularity, such as the finger, nose, ear lobe, or forehead. The probes may be reusable or disposable. The advantages of reusable clip probes are that they are more cost-effective compared with disposable adhesive probes, can be rapidly applied, and are amenable to multiple applications in cases of low signal-to-noise ratio at the specified wavelengths. However, disposable probes allow for more secure placement (in case of patient movement) and provide the capability of monitor sites other than acral areas. Although reduced infectious transmission is a purported benefit of disposable probes, evidence is limited, and one must consider that pulse oximetry probes represent a small fraction of anesthetic equipment requiring decontamination.[75] Accordingly, different probe models may be advantageous in specific conditions. For instance, ear and forehead probes may be more reliable during vasoconstriction compared with finger probes, given that the arterial vessels of such regions are less responsive to circulating catecholamines. As an example, in hypotensive patients that require vasopressors, ear and forehead probes may provide more accurate value of S_pO_2, because these areas are less likely to vasoconstrict with endogenous and exogenous catecholamines compared to fingers or toes.[76,77] During hypothermia with secondary vasoconstriction, the forehead probe is more reliable compared with the finger probe.[78,79]

Emerging Techniques: Pulse spectroscopy is a new technique that utilizes hundreds of wavelengths to assess normal and dysfunctional hemoglobins. Initial results are promising with accurate S_pO_2 determinations, as well as COHb and MetHb assessment during normoxia and hypoxia.[80]

Mixed Venous Oxygen Saturation

PHYSIOLOGIC FUNDAMENTALS

Mixed venous oxygen saturation ($S\bar{v}O_2$) is the O_2 saturation of blood at the proximal pulmonary artery. It has been a frequently monitored variable in critically ill patients, since it reflects the average O_2 saturation of the blood returning from the body to the right heart, weighted by the respective regional blood flows. As such, it is a measure of the balance between global oxygen delivery (DO_2) and global oxygen uptake ($\dot{V}_{O_2}$), and a useful resuscitation target.[81] Factors that influence the $S\bar{v}O_2$ can be illustrated through a derivation of the mixed venous O_2 content equation.

$\dot{V}_{O_2}$ (mL/min) is defined as

$$\dot{V}_{O_2} = 10 \times \dot{Q}_T \times (C_aO_2 - C\bar{v}O_2) \qquad (41.6)$$

where $\dot{Q}_T$ is the cardiac output (L/min), and $C\bar{v}O_2$ is the O_2 content of the mixed venous blood (mL/100 mL).

Rearranging Eq. (41.6) to solve for $C\bar{v}O_2$ yields

$$C\bar{v}O_2 = C_aO_2 - \dot{V}_{O_2}/\dot{Q}_T \qquad (41.7)$$

The contribution of dissolved O_2 to the blood O_2 content is small. By expanding the definition of O_2 content (Eq. 41.1) and ignoring the term for dissolved O_2, Eq. (41.7) can be rewritten as

$$S\bar{v}O_2 = S_aO_2 - \dot{V}_{O_2}/(1.34 \cdot Hb \cdot Q_T) \qquad (41.8)$$

Normal values of $S\bar{v}O_2$ range between 65% and 80%.[82,83] Values close to 40% are associated with tissue hypoxia, anaerobic metabolism, and lactate production. $P\bar{v}O_2$ can be derived from $S\bar{v}O_2$ values by utilizing the O_2Hb dissociation curve adjusted to mixed-venous pH, PCO_2, and temperature (see Fig. 41.2). The normal value of $P\bar{v}O_2$ is 40 mm Hg.

DO_2 is defined as

$$DO_2 = Q_T \times C_aO_2 \qquad (41.9)$$

As is evident from Eq. (41.8), a low $S\bar{v}O_2$ indicates either a reduction in DO_2 secondary to low S_aO_2, low Hb, or low $\dot{Q}_T$, or an increase in $\dot{V}_{O_2}$. The association among $S\bar{v}O_2$, DO_2, and $\dot{V}_{O_2}$ can be illustrated by expressing $S\bar{v}O_2$ as a function of the O_2 extraction ratio, ERO_2.

$$ERO_2 = \dot{V}_{O_2}/DO_2 \qquad (41.10)$$

Expanding the terms yields

$$ERO_2 = 1 - C\bar{v}O_2/C_aO_2 \qquad (41.11)$$

Assuming that the O_2 dissolved in plasma is a negligible component to total O_2 content dissolved in the arterial or mixed venous blood, Eq. (41.11) can be rewritten as

$$ERO_2 = 1 - S\bar{v}O_2/S_aO_2 \qquad (41.12)$$

For conditions in which the arterial blood is fully saturated, Eq. (41.12) may be further simplified:

$$ERO_2 = 1 - S\bar{v}O_2 \qquad (41.13)$$

Solving for $S\bar{v}O_2$ yields

$$S\bar{v}O_2 = 1 - ERO_2 \qquad (41.14)$$

Thus a reduction in $S\bar{v}O_2$ results from an increase in ERO_2, from either an increased $\dot{V}_{O_2}$ or a decreased DO_2 (Fig. 41.7). A decrease in DO_2 occurs in conditions such as hemorrhagic or hypovolemic shock. An increase in $\dot{V}_{O_2}$ may occur in conditions such as stress, pain, shivering, sepsis, and thyrotoxicosis. Conversely, an increase in $S\bar{v}O_2$ indicates either an increase in O_2 supply (elevated S_aO_2, Hb, or $\dot{Q}_T$) or a reduction in $\dot{V}_{O_2}$, as occurs during hypothermia.

There are some subtle considerations in the interpretation of changes in $S\bar{v}O_2$. At PO_2 values typical of venous blood, small increases in the fraction of inspired oxygen (F_IO_2) can cause significant increases in $S\bar{v}O_2$ because of the shape of the O_2Hb dissociation curve (Fig. 41.2). Therefore, when $S\bar{v}O_2$ is tracked as a measure of cardiac function, changes in F_IO_2 must be taken into account during its interpretation.[84] In the setting of septic shock, impairment in O_2 extraction may yield normal $S\bar{v}O_2$ values, despite the presence of tissue hypoxia.

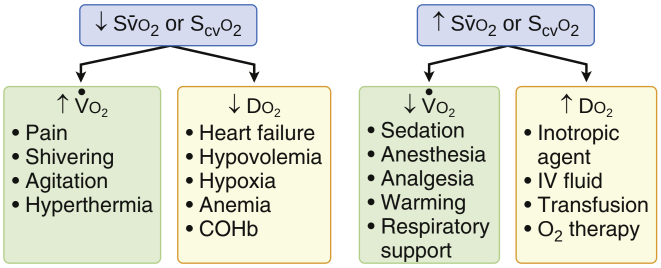

Fig. 41.7 Mixed venous saturation is a measure of the balance between global oxygen delivery and uptake. Conditions which increase $\dot{V}_{O_2}$ or decrease DO_2 will lead to a reduction in $S\bar{v}O_2$. Conversely, conditions which decrease $\dot{V}_{O_2}$ or improve DO_2 will lead to an increase in the $S\bar{v}O_2$. (Modified from Shepherd SJ, Pearse RM. Role of central and mixed venous oxygen saturation measurement in perioperative care. *Anesthesiology*. 2009;111:649–656.)

Direct measurement of $S\bar{v}O_2$ requires the insertion of a pulmonary artery catheter, a procedure associated with some morbidity. However, in most clinical situations, the O_2 saturation of a blood sample drawn from a central venous catheter will suffice. Thus the use of central venous saturation can be a surrogate for $S\bar{v}O_2$. The saturation of blood at the level of a central venous catheter placed in the superior vena cava ($S_{cv}O_2$) reflects the balance between O_2 supply and demand in the brain and upper extremities. Under normal physiologic conditions, $S_{CV}O_2$ is typically 2% to 5% less than $S\bar{v}O_2$, primarily because of the higher O_2 content of splanchnic and renal venous blood.[85] However, during hemodynamic instability, as circulation is redistributed to the upper body, the relationship between $S\bar{v}O_2$ and $S_{CV}O_2$ may reverse, and the difference between the two may increase significantly.[86-88] Although trends in $S_{CV}O_2$ may reflect those in $S\bar{v}O_2$, the two measures cannot be used interchangeably.[88-96]

Mixed venous CO_2 has been used to compute the arteriovenous CO_2 difference ($\Delta PCO_2 = P\bar{v}CO_2 - P_aCO_2$). In conditions of steady-state CO_2 production, ΔPCO_2 changes inversely and nonlinearly with cardiac output as a result of the Fick equation.[97] Accordingly, ΔPCO_2 is an indicator of the adequacy of cardiac output to provide adequate clearance of tissue CO_2. However, because of several limitations, the parameter has not yet found widespread clinical use.[97]

MEASUREMENT PRINCIPLES

The measurement of venous O2 saturation can be performed intermittently by co-oximetry of blood sampled from the distal tip of a pulmonary artery catheter ($S\bar{v}O_2$) or a central venous catheter ($S_{CV}O_2$). Falsely increased values can occur in the presence of a wedged pulmonary artery tip, mitral regurgitation, or left-to-right shunts.[98] Venous saturations can also be measured continuously by spectrophotometry using specialized fiberoptic catheters, which transmit infrared light and detect the amount of light reflected from red blood cells.[99,100] Specialized venous oximetry catheters are available for both pulmonary artery and central venous monitoring and have the advantage of providing continuous measurements of O_2 saturation. Their disadvantage is the cost. Although continuous venous oximetry catheters trend changes, their reported absolute values are not equivalent to concurrently obtained co-oximetry measurements.[101-103]

APPLICATIONS AND INTERPRETATION

In patients undergoing major abdominal or cardiac surgery, intraoperative reductions in $S\bar{v}O_2$ and $S_{CV}O_2$ have been associated with postoperative complications.[104-108] Protocol-based interventions that target specific values of $S\bar{v}O_2$ or $S_{CV}O_2$ have been shown to reduce the length of stay, organ dysfunction, and mortality in patients undergoing major surgery and patients presenting with sepsis.[109-111] Goal-directed therapy based on $S_{cv}O_2$ has been advocated for the management of sepsis, and the implementation of such protocols is associated with improvements in mortality.[112,113] The use of $S_{CV}O_2$ as a therapeutic endpoint remains controversial for several reasons: $S_{CV}O_2$ may be increased in sepsis because of impaired tissue O_2 extraction[114]; the increased cost associated with the use of $S_{CV}O_2$-measuring catheters[115]; and other measures, such as lactate clearance, are less costly while leading to similar outcomes.[116] Furthermore, the management of sepsis without an $S_{CV}O_2$ endpoint can yield equally favorable results.[115] The difference between $S\bar{v}O_2$ and $S_{CV}O_2$ has been proposed as a marker of complications after cardiac surgery.[117]

Tissue Oxygenation

Arterial and venous O_2 saturations are measures of DO_2 and uptake by the whole body. Although useful, these global measures do not provide information regarding organ or tissue oxygenation, which reflects the important local balance between O_2 supply and demand. Regional O_2 balance can differ both among organs as well as within regions of the same organ.[118] Current noninvasive methods for the assessment of microcirculatory oxygenation make use of reflectance spectroscopy using light either in the visible spectrum (VLS) or in the near-infrared spectrum (NIRS). A recent technique based on the protoporphyrin IX triplet state lifetime aims at the assessment of mitochondrial O_2 tension in vivo, and opens the prospect of future clinical monitoring (see Fig. 41.1).[119]

Reflectance spectroscopy probes have light emitters and receivers positioned in line (Fig. 41.8). When they are placed on a tissue surface, light transmission through the tissue is affected by reflection, absorption, and scatter. Reflection depends on the angle of incidence of the light beam and the wavelength of light, whereas scatter depends on the number and type of tissue interfaces. As previously outlined, the Beer-Lambert law relates the absorption of light by the tissue to the concentration of tissue chromophores, the extinction coefficient of each, and the pathlength of the light through the tissue.[120] The predominant tissue chromophore is hemoglobin. The pathlength of the light is affected by both reflection and scatter, so it cannot be measured directly, but rather must be estimated. Most of the detected photons travel in an arc between the two detectors (see Fig. 41.8). The depth of penetration of the arc into the tissue is proportional to the wavelength of light and the distance between the transmitter and detector.[120,121]

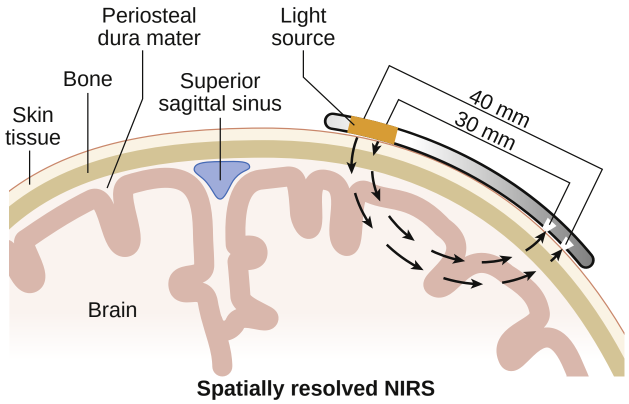

Fig. 41.8 Near Infrared Spectroscopy Applied to Cerebral Oximetry. In this case, a reflectance oximeter is placed on the forehead. Near infrared wavelength light is emitted from the light source and enters the underlying tissue. Light is scattered, reflected, and absorbed. Light that reaches the photodetector travels an arc-shaped path. The depth of the path is a function of the distance between the emitter and the detector. The measured value is the oxygen saturation of the tissue through which the light travels on its way to the detector. It is a primarily venous-weighted value. *NIRS*, Near infrared spectroscopy. (Redrawn from Casati A, Spreafico E, Putzu M, et al. New technology for noninvasive brain monitoring: continuous cerebral oximetry. *Minerva Anestesiol.* 2006;72:605–625.)

VLS makes use of white light with wavelengths of 500 to 800 nm, whereas NIRS employs light in the 700 to 1100 nm range.[122] In general, the depth of penetration of VLS is less than that of NIRS, thus allowing superficial measurements of up to 16 mm and making it suitable for measurements of small subsurface volumes. NIRS can penetrate tissue to a depth of several centimeters and allows sampling of a larger volume of tissue.[123] The O_2 saturation displayed is that of a volume of tissue. This volume includes arteries, capillaries, and veins, and has a predominantly venous weighting.[124]

CLINICAL APPLICATIONS

A number of applications have been described for VLS. Buccal microvascular Hb saturation has been associated with survival in patients with sepsis.[125] VLS has also been used for monitoring flap viability following reconstructive surgery.[126] During gastrointestinal and esophageal surgery, reductions in gastrointestinal tissue saturation, measured by VLS, have been associated with postoperative anastomotic complications.[127,128] Endoscopic VLS differentiates between normal and ischemic areas of colon,[129] and it may be useful for the diagnosis of mesenteric ischemia.[130] In addition, mucosal O_2 saturation of the gastric conduit following esophagectomy is useful and explores the benefits of ischemic preconditioning.[131]

The most widespread application of NIRS has been in cerebral oximetry,[118] with probes placed on the forehead to measure frontal cortical oxygenation (rSO_2). Several NIRS systems are commercially available, with each manufacturer offering a different specific technology. As there is no gold standard for cerebral oximetry, it is difficult to compare the accuracy of the devices. Furthermore, each device has its own set of "normal" values. For this reason, acquisition of baseline values for each patient at the start of the procedure has been recommended.[132] Typical values of rSO_2 range from 51% to 82% with a mean baseline of 66%.[133] A reduction of rSO_2 below 20% to 25% of the baseline, or lower than an absolute value of 50%, is a suggested threshold for intervention.[134,135]

The utility of cerebral oximetry has been explored in cardiovascular, abdominal, thoracic, and orthopedic surgery. In the cardiac surgical setting, intraoperative reductions in rSO_2 have been associated with early postoperative cognitive dysfunction and prolonged ICU and hospital lengths of stay.[135-138] Baseline rSO_2 measurements have been associated with 30-day mortality after left ventricular assist device surgery.[139] As a guide to therapy, interventions for rSO_2 reductions less than 75% of baseline in patients undergoing coronary artery bypass graft surgery have been shown to significantly reduce the incidence of major organ morbidity and mortality, as well as ICU length of stay.[134]

During carotid endarterectomy, intraoperative reductions in rSO_2 correlate well with changes in transcranial Doppler measurements,[140-144] electroencephalographic waveforms,[145-147] and stump pressure[144,148,149], which are consistent with ischemia. Although some studies indicate that reductions in rSO_2 that are less than 20% of baseline are well tolerated, data are lacking for a clear rSO_2 threshold for carotid shunt placement.[150,151] NIRS has also been preliminarily used during and following ICU open thoracoabdominal aortic aneurysm repair for continuous monitoring of spinal cord oxygenation[152].

In elderly patients undergoing major abdominal surgery, protocol-based intraoperative treatment of reductions in rSO_2 results in decreases in postoperative cognitive decline and hospital length of stay.[153] In patients undergoing thoracic surgical procedures with single-lung ventilation, early postoperative cognitive dysfunction is directly related to intraoperative exposure time to rSO_2 less than 65%.[154] Patients undergoing shoulder surgery in the beach chair position have a lower baseline rSO_2 and a larger number of episodes of cerebral desaturation, although the clinical implications of these findings are unclear.[155-157]

Shock is a condition in which patients may have inadequate *regional* perfusion in the setting of normal *global* perfusion parameters. In such circumstances, the use of NIRS to monitor tissue perfusion holds some promise. Values obtained by the application of an NIRS probe to the thenar eminence (S_tO_2) discriminate between healthy volunteers and patients with shock.[158] Furthermore, in patients with major trauma who present with shock, S_tO_2 values can identify patients who proceed to develop multiorgan dysfunction or actually die.[159,160]

Overall, available information is still limited to warrant clinical decision making exclusively based on NIRS measurements. Currently there is insufficient evidence to support the use of perioperative NIRS monitoring in adults to reduce short-term or mild postoperative cognitive dysfunction, postoperative stroke, delirium, or death.[161] Of note, in a 2015 retrospective study, patients who self-identified as African American had lower rSO_2 compared with those who self-identified as Caucasian, a finding attributed to light attenuation by skin pigmentation.[162] Further investigations are necessary to improve our understanding of NIRS and its relevance for clinical management.

Capnometry and Capnography

GENERAL CONCEPTS

The presence CO_2 in exhaled breath reflects the fundamental physiologic processes of ventilation, pulmonary blood flow, and aerobic metabolism. Its continued monitoring ensures the anesthesiologist of correct placement of an endotracheal tube (ETT) or laryngeal mask airway (LMA), as well as the integrity of a breathing circuit. Exhaled CO_2 provides information primarily on ventilation. It is also used to estimate the adequacy of cardiac output. In combination with P_aCO_2, exhaled CO_2 can be used to estimate the ratio of physiologic dead space (V_D) to tidal volume (V_T) by using the Bohr equation[163]:

$$\frac{V_D}{V_T} = \left(\frac{P_aCO_2 - P_{\bar{E}}CO_2}{P_aCO_2}\right) \qquad (41.15)$$

where $P_{\bar{E}}CO_2$ is the mixed expired CO_2 partial pressure, such as measured in exhaled air collected in a mixing bag chamber, or computed from a volumetric capnogram. The ability to detect and quantify CO_2 is a crucial component of respiratory monitoring in anesthesia and critical care medicine.

Considerable confusion arises from inconsistent and interchangeable terminology as applied to medical CO_2 gas analysis.[163-165] In a very general sense, *capnometry* refers to the measurement and quantification of inhaled or exhaled CO_2 concentrations at the airway opening. *Capnography*, however, refers not only to the method of CO_2 measurement, but also to its graphic display as a function of time or volume. A *capnometer* is simply a device that measures CO_2 concentrations. A capnometer may display a numeric value for inspired or exhaled CO_2. A *capnograph*, however, is a device that records and displays CO_2 concentrations, usually as a function of time. A *capnogram* refers to the graphic display that the capnograph generates. Fig. 41.9 illustrates a typical CO_2 concentration profile for three breaths as a function of time.

MEASUREMENT PRINCIPLES

Various methods exist for detecting and quantifying CO_2 concentrations in respiratory gases, such as mass spectrometry, Raman spectrometry, or gas chromatography.[166,167] The most commonly used method in clinical environments relies on nondispersive infrared absorption.[168] With this technique, a beam of infrared light is passed through a gas sample, and the resulting intensity of the transmitted light is measured by a photodetector.[164] Gaseous CO_2 absorbs light over a very narrow bandwidth centered around 4.26 µm. Its presence in the sample cell decreases the amount of infrared light at this wavelength that reaches the detector in proportion to its concentration. Because the absorption spectrum for CO_2 partially overlaps with the spectra of other gaseous species commonly encountered in anesthesia (i.e., water and nitrous oxide[169]), infrared filters and

compensation algorithms are used to minimize this interference and improve accuracy.[170]

Most capnometers rely on infrared-light source that is focused on a chopper disk that rotates at approximately 60 revolutions per second. The chopper allows the beam to be alternately directed through (1) the sample cell with the gas to be analyzed and (2) a reference cell with no detectable CO_2. In addition, the light source is completely blocked at various points during the revolution of the chopper disk. The photodetector and associated circuitry process these three signals to estimate the changes in CO_2 concentration continuously in the sample cell. Alternatively, CO_2 concentration may be estimated with solid-state technology, using a beam splitter instead of a chopper wheel. The splitter allows for the measurement of infrared energy at wavelengths within and outside the absorption spectrum of CO_2.

Capnometers fall into two general categories: sidestream (diverting) and mainstream (nondiverting). Sidestream analyzers are more frequently used in clinical environments. Their CO_2 sensors are physically located away from the airway gases to be measured. Sidestream analyzers incorporate a pump or compressor that aspirates gases into a sample cell located at the unit's console (Fig. 41.10*A*). Typical tubing length for this aspiration may be 6 feet, and gas withdrawal rates may vary from 30 to 500 mL/min. This lost gas volume may need to be considered during closed-circuit anesthesia or during ventilation of neonates and infants. The volume can be returned to the circuit, or it can be routed to a scavenger to prevent contamination of the environment with anesthetic or waste gases. Gases must also pass through various filters and water traps before they are presented to the sample cell.[164] Sidestream capnometers have a transport delay time corresponding to the rate at which gas is sampled and the washout of the analyzing chamber (see Fig. 41.10*B*). The capnograms generated by sidestream analyzers also have an associated rise time, defined as the time required for the analyzer to respond to a sudden change in CO_2 concentration.[171] By convention, this is usually the time interval required for the for the analyzer output to change from 10% to 70% of its final value.[*,171] Typical rise times for commercially available capnometers range from 10 to 400 ms, and they can depend on the rotation of the chopper wheel, the rate of gas aspiration, the volume of aspiration tubing and water traps, and the dynamic response of the infrared filters and other electronics.

With mainstream analyzers, the sample cell is placed directly into the patient's breathing circuit. Thus the inspiratory or expiratory gases pass directly through the infrared light path (see Fig. 41.10*C*). An advantage of mainstream analyzers is that they have no delay time (see Fig. 41.10*D*). Moreover, their rise time is generally faster than that of sidestream analyzers.[171] A disadvantage is the potential increase in dead space, although recent developments in solid-state electronics have made this much less of an issue.[172] In addition, the sample cell is usually heated to 40°C to minimize the condensation of water vapor, which can bias the measurement. This increase in temperature, combined with the proximity of the sensor to the patient's airway, can potentially increase the risk of facial burns.

TIME CAPNOGRAM

The simplest and most widely used form of display for exhaled CO_2 is the *time capnogram*. The time capnogram displays both inspiratory and expiratory phases. Fig. 41.9 shows a typical time capnogram for three breaths. The expiratory phase is divided into three distinct components. Phase I corresponds to the exhalation of dead space gas from the central conducting airways or any equipment distal to the sampling site, which ideally should have no detectable CO_2 (i.e., partial pressure of CO_2, $PCO_2 \sim 0$). During phase II, a sharp rise in PCO_2 to a plateau indicates the sampling of transitional gas between the airways and alveoli. The plateau region of the capnogram, phase III, corresponds to the PCO_2 in the alveolar compartment. For a lung with relatively homogeneous ventilation, phase III is approximately flat throughout expiration. In fact, various mechanisms contribute to the slight upsloping of CO_2 concentration versus time during phase III. Most of these mechanisms reflect a heterogeneous distribution of ventilation-perfusion ($\dot{V}/\dot{Q}$) or alveolar CO_2 partial pressure (P_ACO_2) throughout the lung. Well-ventilated and well-matched $\dot{V}/\dot{Q}$ regions tend to have lower PCO_2 and shorter time constants, and they empty earlier during the expiratory phase. Less well-ventilated and poorly matched $\dot{V}/\dot{Q}$ regions have higher CO_2 levels, and they empty later in the expiratory cycle. Respiratory pathologies associated with an increase in ventilation heterogeneity, such as asthma, chronic obstructive pulmonary disease (COPD), or acute lung injury,[173] yield a steeper upslope of phase III. Interventions that improve ventilation

homogeneity, such as positive end-expiratory pressure (PEEP) or bronchodilators, flatten phase III. Mechanical disturbances may also be present during phase III, reflecting processes such as spontaneous breathing efforts, cardiogenic oscillations, or surgical manipulation (Fig. 41.11). Following phase III, a sharp downstroke of PCO_2 occurs as fresh inspired gas moves past the sampling site and washes out the remaining CO_2. This is referred to as the beginning of phase 0 by some authors,[165,174] or phase IV by others.[166] Occasionally, a sharp upstroke in PCO_2 is observed at the very end of phase III, which is termed phase IV or IV′, depending on the author.[175] This upstroke probably results from the closure of lung units with relatively low PCO_2 and allows for regions of higher CO_2 to contribute a greater proportion of the exhaled gas to be sampled.[165] Additional insights into various abnormalities in ventilation or perfusion are also obtained by trending time capnograms over many breaths for long periods (Fig. 41.12).

The term "end-tidal" CO_2 ($P_{ET}CO_2$) generally refers to the final value of the exhaled PCO_2 curve, at the very end of the expiratory phase. The method used to determine this number is not universal, and varies according to the manufacturer of the particular capnograph in use. For example, $P_{ET}CO_2$ may simply be (1) the PCO_2 value just before inspiration, (2) the largest PCO_2 value during a single exhalation cycle, or (3) the PCO_2 value at a specified time in the capnogram averaged across several breaths. If $P_{ET}CO_2$ is measured during a reasonably flat and undistorted phase III, it may be well correlated with P_aCO_2.[170] This may not be the case if the duration of phase III is truncated, or if CO_2 is measured from gas that is contaminated with room or O_2-enriched air (i.e., during spontaneous breathing with a nasal cannula or facemask). Potential causes of increased or decreased $P_{ET}CO_2$ are listed in Table 41.2. In healthy individuals with homogeneous ventilation, the difference between P_aCO_2 and $P_{ET}CO_2$ is usually less than 5 mm Hg, thereby expressing the equilibration between alveolar and pulmonary capillary blood. Several disease states compromise this equilibration and produce increased $P_aCO_2 - P_{ET}CO_2$ difference (Box 41.2). There are situations in which $P_{ET}CO_2$ can be greater than P_aCO_2, especially in the presence of severe ventilation heterogeneity and lung units with very low $\dot{V}/\dot{Q}$. For steady-state conditions, the $P_{ET}CO_2$ usually reflects the relative balance between CO_2 production and alveolar ventilation.

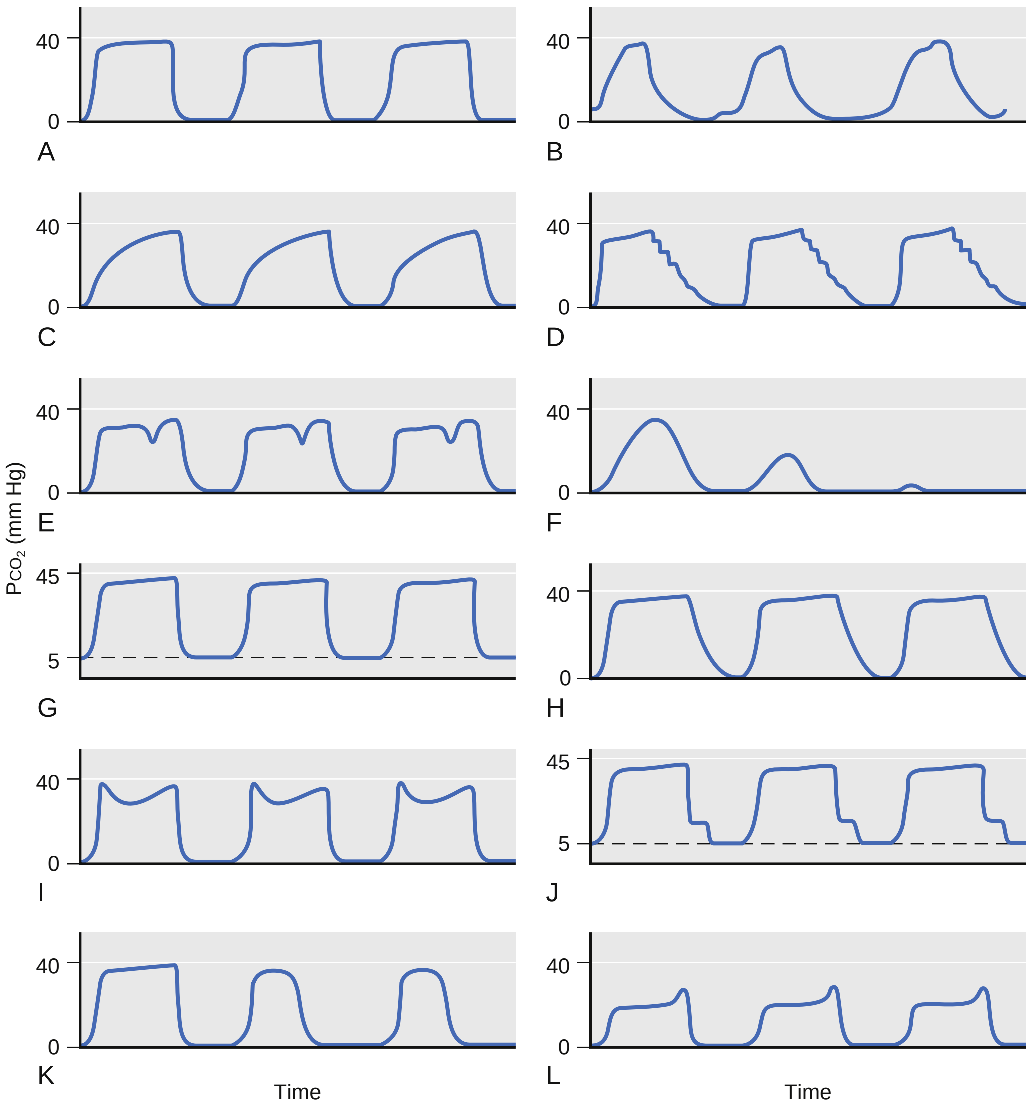

Fig. 41.11 Representative Time Capnograms under Normal and Abnormal Conditions. (A) Normal capnogram during controlled mechanical ventilation; (B) normal capnogram during spontaneous breathing; (C) increased upslope of phase III, as may occur during bronchospasm (asthma, chronic obstructive pulmonary disease), or partially obstructed endotracheal tube/breathing circuit; (D) cardiogenic oscillations at the end of exhalation as flow decreases to zero and the beating heart causes emptying of different lung regions and back-and-forth motion between exhaled and fresh gas; (E) clefts during phase III indicating spontaneous breathing efforts during controlled mechanical ventilation; (F) esophageal intubation; (G) rebreathing of CO_2, as may occur with faulty expiratory valve or exhausted absorber system. Inspiratory CO_2 is consistently above 0; (H) faulty inspiratory valve, resulting in a slower downslope, which extends into the inhalation phase (phase 0) as CO_2 in the inspiratory limb is rebreathed; (I) two peaks in phase III suggestive of sequential emptying of two heterogeneous compartments, as may be seen in a patient with a single lung transplant; (J) faulty inspiratory valve; (K) sudden shortening of the duration of phase III during controlled mechanical ventilation, suggesting the abrupt onset of a ruptured or leaking endotracheal tube cuff; (L) dual plateau in phase III, suggesting the presence of a leak in a sidestream sample line. Early portion of phase III abnormally low due to dilution of exhaled gas with ambient air. The sharp increase in CO_2 at the end of phase III reflects a diminished leak resulting from the increased circuit pressure at the onset of inspiration. *PCO_2*, **Partial pressure of carbon dioxide.** (Modified from Hess D. Capnometry and capnography: technical aspects, physiologic aspects, and clinical applications. *Respir Care*. 1990;35:557–576; Roberts WA, Maniscalco WM, Cohen AR, et al. The use of capnography for recognition of esophageal intubation in the neonatal intensive care unit. *Pediatr Pulmonol*. 1995;19:262–268; and Eskaros SM, Papadakos PJ, Lachmann B. VOLUME CAPNOGRAM

Although time capnography is relatively straightforward to monitor in clinical environments, a major limitation of the technique is its lack of information regarding respiratory flows or volumes.[174] The *volume capnogram* is a graphic display of CO_2 concentration or partial pressure versus exhaled volume.[166] The inspiratory phase is not defined in a volume capnogram. Similar to its temporal counterpart, it is also partitioned into three distinct phases (I, II, and III) corresponding to anatomic dead space, transitional, and alveolar gas samples (Fig. 41.13). However, it possesses several advantages over the time capnogram. First, it allows for estimation of the relative contributions of anatomic and alveolar components of physiologic dead space.[175a,176] Second, it is more sensitive than the time capnogram in detecting subtle changes in dead space that are caused by alterations in PEEP, pulmonary blood flow, or ventilation heterogeneity (Fig. 41.14). Finally, the numeric integral of PCO_2 as a function of volume allows for determination of

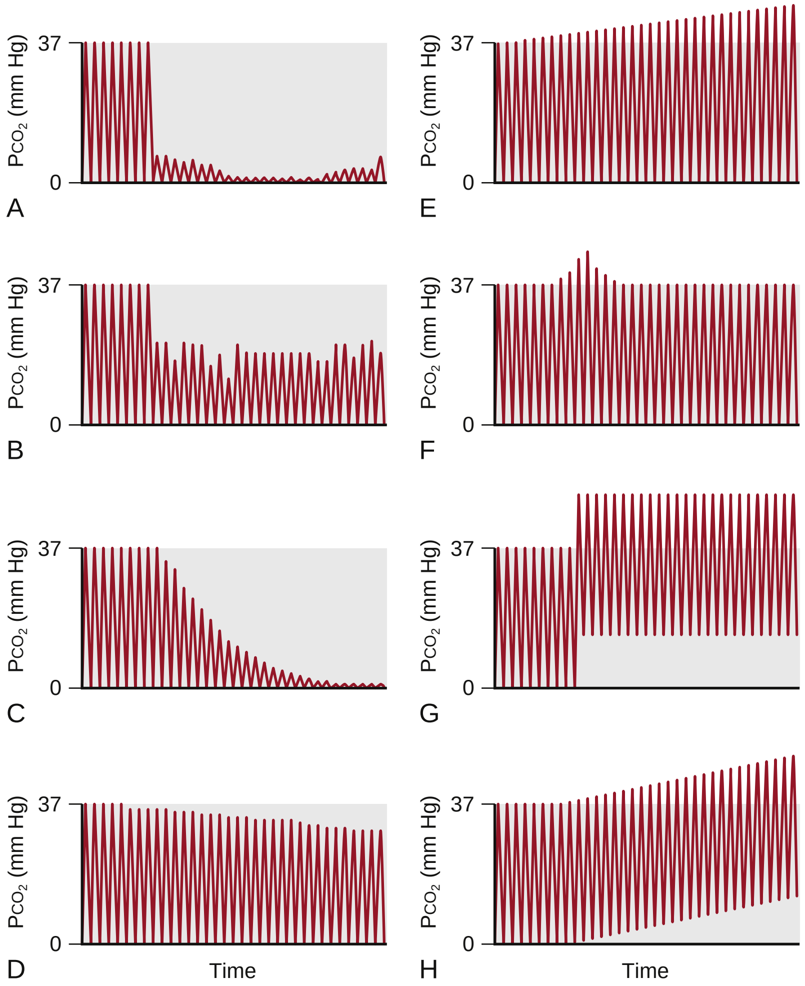

Fig. 41.12 Representative time capnograms trended over many breaths, illustrating various abnormalities in ventilation and/or perfusion. (A) sudden drop in CO_2 due to catastrophic loss of ventilation; (B) leak or partial obstruction in breathing circuit; (C) sudden interruption in pulmonary perfusion, as may occur during cardiac arrest; (D) gradual decrease in CO_2 due to hyperventilation, decreased metabolism, or decreased pulmonary perfusion; (E) gradual increase in CO_2 as may occur during hypoventilation, laparoscopic insufflation, increased metabolism, or increased pulmonary perfusion; (F) transient rise in CO_2 indicated acute increase in CO_2 delivery to the lungs, as may occur during release of a tourniquet or administration of a bicarbonate bolus; (G) rise in both the baseline and end-tidal CO_2, consistent with a contaminated sample cell; (H) gradual rise in baseline and end-tidal CO_2, consistent with rebreathing. *PCO_2*, Partial pressure of CO_2. (Modified from Swedlow DB. Capnometry and capnography: the anesthesia disaster early warning system. *Semin Anesth*. 1986;5:194–205.)

the total mass of CO_2 exhaled during a breath and provides for the estimation of $\dot{V}_{CO_2}$.

Blood Gas Analysis

PHYSIOLOGIC FUNDAMENTALS

Arterial blood gas analysis is used to assess oxygenation, ventilation, and acid-base status. This section focuses on the use of arterial blood gases to assess oxygenation and ventilation. For a discussion of acid-base status, see Chapter 48, "Perioperative Acid-Base Balance."

Oxygenation is reflected in the P_aO_2, which is a function of the alveolar partial pressure of O_2 (P_AO_2) and the efficiency of O_2 transfer from alveoli to the pulmonary capillary blood. In healthy adults breathing room air at sea level, P_aO_2 ranges between 80 and 100 mm Hg. The normal value of P_aO_2 decreases with increasing age and increasing altitude. Hypoxemia is defined as a P_aO_2 less than 80 mm Hg. There are five physiologic causes of hypoxemia: (1) hypoventilation, (2) $\dot{V}/\dot{Q}$ mismatching, (3) right-to-left shunt, (4) diffusion limitation, and (5) diffusion-perfusion mismatch. The first three causes explain the majority of hypoxemia in the perioperative setting. Reduced inspired PO_2 (e.g., in faulty closed or partially closed anesthesia breathing circuits or at high altitude) is an additional cause of hypoxemia.

These factors produce hypoxemia by affecting different steps of O_2 transport from the environment to the arterial blood. A low inspired PO_2, as well as hypoventilation, reduces the P_AO_2. $\dot{V}/\dot{Q}$ mismatch, right-to-left shunt, and alveolar diffusion limitation affect the efficiency of O_2 exchange. Diffusion limitation plays a role in conditions that thicken the alveolar-capillary barrier, such as interstitial lung diseases, and in hypoxemia induced by exercise or altitude.[177,178] In the clinical setting, impairment of diffusion of O_2 or CO_2 rarely occurs to a significant extent. The remainder of this section focuses on $\dot{V}/\dot{Q}$ mismatch and right-to-left shunt.

TABLE 41.2 Causes of Changes in Partial Pressure of End-Tidal Carbon Dioxide

↑$P_{ET}CO_2$	↓$P_{ET}CO_2$
↑CO_2 Production and Delivery to the Lungs	**↓CO_2 Production and Delivery to the Lungs**
Increased metabolic rate	Hypothermia
Fever	Pulmonary hypoperfusion
Sepsis	Cardiac arrest
Seizures	Pulmonary embolism
Malignant hyperthermia	Hemorrhage
Thyrotoxicosis	Hypotension
Increased cardiac output (e.g., during CPR)	
Bicarbonate administration	
↓Alveolar Ventilation	**↑Alveolar Ventilation**
Hypoventilation	Hyperventilation

BOX 41.2 Causes of Increased Arterial-to-End-Tidal Carbon Dioxide Pressure Difference $P_{(a-ET)CO2}$

- Increased ventilation-perfusion heterogeneity, particularly with high V/Q regions
- Pulmonary hypoperfusion
- Pulmonary embolism
- Cardiac arrest
- Positive pressure ventilation (especially with PEEP)
- High-rate low-tidal-volume ventilation

PEEP, Positive end-expiratory pressure. Modified from Hess D. Capnometry and capnography: technical aspects, physiologic aspects, and clinical applications. *Respir Care*. 1990;35:557–576.

$\dot{V}/\dot{Q}$ mismatch is the most common cause of hypoxemia in the clinical setting. Ventilation and perfusion are nonuniformly distributed throughout the normal lung, with worsening mismatch in the setting of lung disease, general anesthesia, and mechanical ventilation. Areas with low or zero $\dot{V}/\dot{Q}$ yield low end-capillary PO_2, whereas areas with normal or high $\dot{V}/\dot{Q}$ produce higher end-capillary PO_2. However, because of the plateau of the O_2Hb dissociation curve (see Fig. 41.2), the normal and high $\dot{V}/\dot{Q}$ regions are limited in the extent to which they increase the O_2 content and compensate for the low $\dot{V}/\dot{Q}$ regions (Fig. 41.15). Consequently, $\dot{V}/\dot{Q}$ mismatch results in hypoxemia.

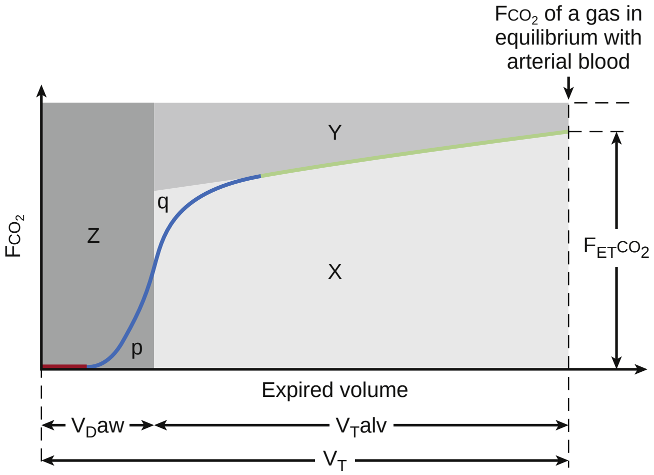

Fig. 41.13 The volume capnogram is a plot of the fraction of CO_2 *(FCO_2)* in exhaled gas versus exhaled volume. It is divided into three phases, which reflect the same sources of expired gas as present in the time capnograph: anatomic dead space (phase I, *red*), transitional (phase II, *blue*), and alveolar gas (phase III, *green*). The volume capnogram allows for the partition of total tidal volume *(V_T)* into airway dead space volume *(V_Daw)* and an effective alveolar tidal volume *(V_Talv)* by a vertical line through Phase II, positioned such that the approximately triangular areas p and q are equal. It also provides the slope of phase III as a quantitative measure of the heterogeneity of alveolar ventilation. The total area below the horizontal line (denoting the FCO_2 of a gas in equilibrium with arterial blood) can be divided into three distinct areas: *X*, *Y*, and *Z*. Area X corresponds to the total volume of CO_2 exhaled over a tidal breath. This value can be used to compute the CO_2 production ($\dot{V}_{CO_2}$), and the mixed expired CO_2 fraction or partial pressure to be used in the Bohr equation (Eq. [41.15]) based on the division of the exhaled CO_2 volume by the exhaled tidal volume. Area Y represents wasted ventilation due to alveolar dead space, while area Z corresponds to wasted ventilation due to anatomic deadspace (V_Daw). Thus areas Y + Z represent the total physiologic dead space. The volume capnogram can also be plotted as a PCO_2 versus exhaled volume curve. *$F_{ET}CO_2$*, Fraction of end-tidal carbon dioxide. (Modified from Fletcher R, Jonson B, Cumming G, et al. The concept of deadspace with special reference to the single breath test for carbon dioxide. *Br J Anaesth*. 1981;53:77–88.)

Right-to left shunt is the amount of blood that flows from the pulmonary artery to the systemic arterial circulation without undergoing pulmonary gas exchange. It represents an extreme case of $\dot{V}/\dot{Q}$ mismatch in which the ratio equals zero and the end-capillary gas partial pressures are equal to the values found in mixed venous blood. In healthy awake spontaneously breathing subjects, intrapulmonary shunt is negligible,[179] and a small (<1% of cardiac output) extrapulmonary shunt results from drainage of the bronchial and Thebesian veins into the arterial side of the circulation.[180] During general anesthesia, a right-to-left shunt can develop as a result of atelectasis.[181,182] Right-to-left shunt can also be seen in pathologic conditions such as pneumonia and acute lung injury. The effect of the shunt on P_aO_2 is a function of the magnitude of the shunt, F_IO_2, and the cardiac output (Fig. 41.16). Importantly, increases in F_IO_2 have a small effect on P_aO_2 in the presence of large true right-to-left shunt (see Fig. 41.16).

The traditional method to estimate flow through shunting regions ($\dot{Q}_s$) as a fraction of the total cardiac output ($\dot{Q}_T$) is based on the modeling of the lung as a three-compartment system (Fig. 41.17).[183] The three compartments represent (1) lung regions receiving both ventilation and perfusion,

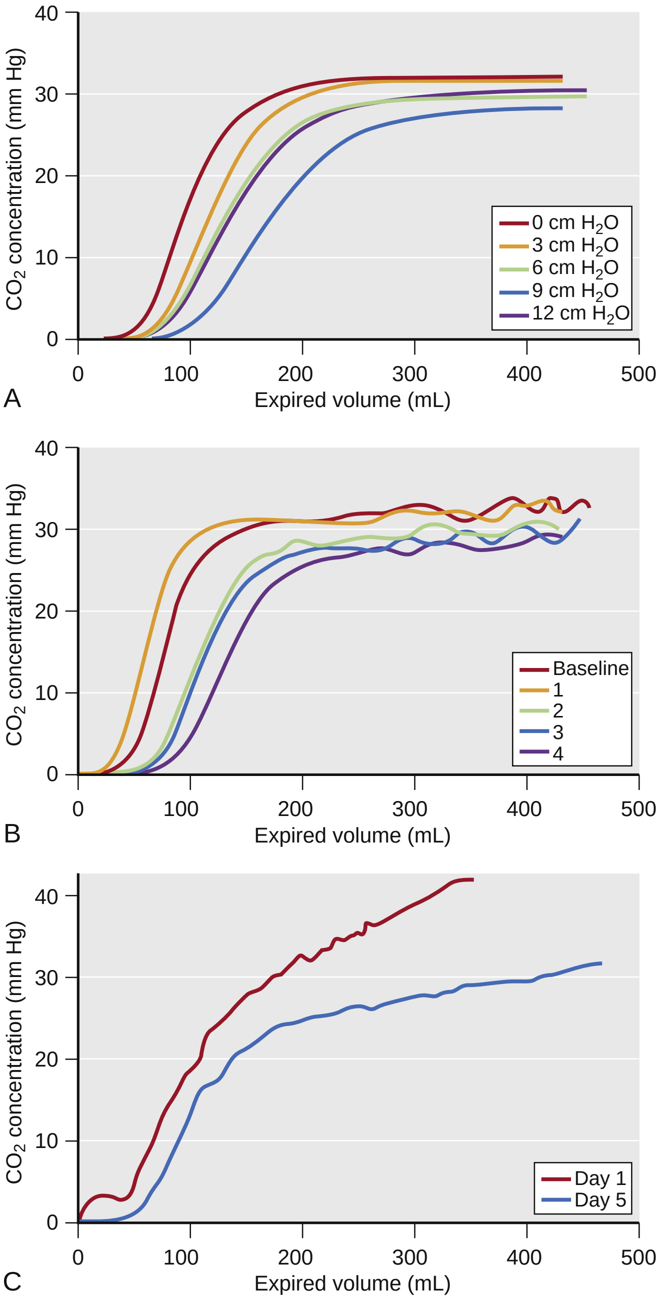

Fig. 41.14 Representative Single-breath Volume Capnograms, Illustrating Various Abnormalities in Ventilation or Perfusion. (A) alterations in phases II and III with corresponding changes in positive end-expiratory pressure (0, 3, 6, 9, and 12 cm H_2O) during positive pressure ventilation; (B) alterations in phases II and III with corresponding changes in pulmonary perfusion (increasing numbers correspond to decreasing pulmonary blood flow); (C) pronounced positive slope of phase III during acute bronchospasm (Day 1). Following resolution (Day 5), there is a noticeable reduction in the slope phase III. ***CO_2*, Carbon dioxide.** (Modified from Thompson JE, Jaffe MB. Capnographic waveforms in the mechanically ventilated patient. *Respir Care*. 2005;50:100–108.)

(2) a shunt compartment ($\dot{V}/\dot{Q} = 0$), and (3) a dead space compartment with ventilation but no perfusion ($\dot{V}/\dot{Q}$ = infinity). The application of the concept of mass balance to this model yields the shunt fraction ($\dot{Q}_s/\dot{Q}_T$) expression

$$\dot{Q}_S/\dot{Q}_T = \frac{(Cc'O_2 - Ca\,O_2)}{(Cc'O_2 - C\bar{v}O_2)} \qquad (41.16)$$

where $\dot{Q}_s$ is the shunted blood flow, and $Cc'O_2$ is the end-capillary O_2 content. $Cc'O_2$ is calculated using Eq. (41.1), assuming equilibration between the end-capillary blood and alveolar gas. The P_AO_2 is calculated using the ideal alveolar gas equation:

$$P_AO_2 = F_IO_2 \cdot (P_{atm} - P_{H_2O}) - P_aCO_2/R \qquad (41.17)$$

where F_IO_2 is the inspired O_2 fraction, P_{atm} is barometric pressure (typically assumed to be the pressure of one standard atmosphere at sea level, 760 mm Hg), and P_{H_2O} is partial pressure of water vapor (47 mm Hg at 37°C). R, the respiratory quotient, is the ratio of pulmonary CO_2 elimination to O_2 uptake ($R = \dot{V}_{CO_2}/\dot{V}_{O_2}$), which equals the value of 0.8 under normal diet and metabolic conditions.

The three-compartment model is a simplification of the real lung. As a result, under conditions of F_IO_2 less than 100%, $\dot{Q}_S/\dot{Q}_T$ computed with Eq. (41.16) represents a combination of all factors producing hypoxemia, predominantly true right-to-left shunt and $\dot{V}/\dot{Q}$ mismatch. Under such conditions, $\dot{Q}_S/\dot{Q}_T$ is referred to as venous admixture. When F_IO_2 is 100%, the effects of $\dot{V}/\dot{Q}$ heterogeneity on O_2 exchange are eliminated and the equation exclusively yields the right-to-left shunt fraction.[184] The administration of 100% O_2 (i.e., F_IO_2 of 1.0) can lead to the development of absorption atelectasis in compartments with very low $\dot{V}/\dot{Q}$, thus leading to an increase in true right-to-left shunt.[184]

If the assumptions are made that end-capillary blood has an O_2 saturation of 100% and the O_2 content of blood is predominantly determined by Hb saturation, the shunt fraction equation can be simplified to

$$\dot{Q}_S/\dot{Q}_T = \frac{(1 - S_aO_2)}{(1 - S\bar{v}O_2)} \qquad (41.18)$$

where S_aO_2 is arterial saturation, and S$\bar{v}$O2 is mixed venous saturation.

Other indices of oxygenation: The calculation of the shunt fraction is a fundamental measure of O_2 exchange impairment. However, a pulmonary artery catheter is required for the measurement of S$\bar{v}$O2. For this reason, indices of oxygenation that rely on less invasive measures have been developed. An ideal index should reflect the efficiency of oxygenation, change with changes in lung function, remain constant with changes in extrapulmonary conditions (such as F_IO_2), and provide clinically useful diagnostic and prognostic information.[185] Although P_aO_2 certainly reflects arterial blood oxygenation, it is limited in providing a measure of the magnitude of the O_2 exchange deficiency because of its dependence on the F_IO_2 and to the nonlinear relationship between P_aO_2 and blood O_2 content.[185] As a consequence, several indices based on the P_aO_2 that account for the F_IO_2 or the P_AO_2 have been developed: the alveolar-arterial partial pressure gradient of O_2 ($[A-a]PO_2$), the respiratory index ($[A-a]PO_2/P_aO_2$), the arterial-alveolar ratio of O_2 partial pressures (P_aO_2/P_AO_2), and the ratio between P_aO_2 and F_IO_2 (P_aO_2/F_IO_2).[185]

The advantages of indices based on P_aO_2 are that their calculations are fairly simple and require only arterial blood sampling. However, an important limitation is that these indices vary with the F_IO_2, P_aCO_2, Hb, and O_2 consumption ($\dot{V}_{O_2}$).[186,187] Consequently, changes in those variables can lead to changes in the values of the indices in the absence of

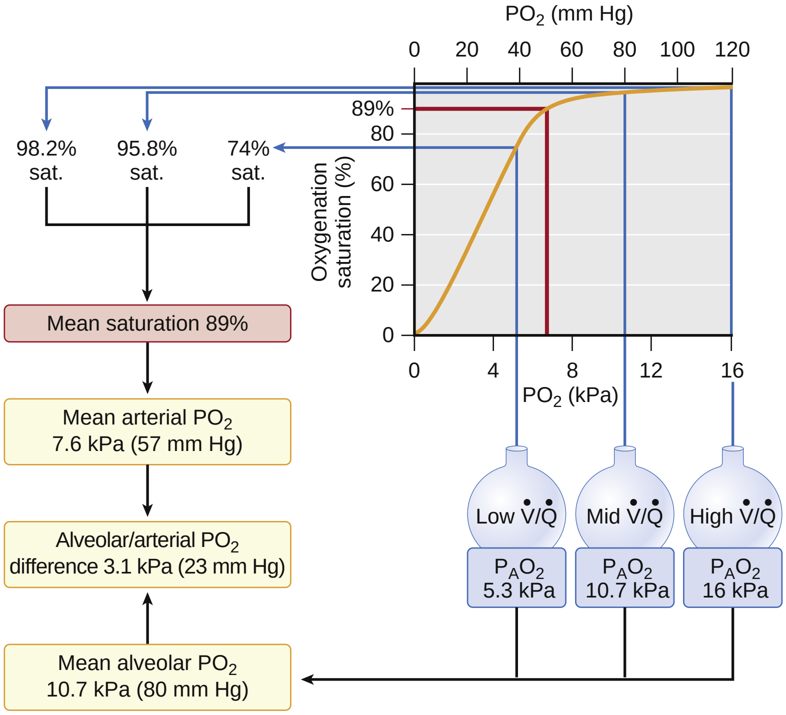

Fig. 41.15 Effect of Different Ventilation-Perfusion ($\dot{V}/\dot{Q}$) Regions on Partial Pressure of Arterial Oxygen (P_aO_2). Because of the shape of the oxyhemoglobin dissociation curve, regions of lung with low $\dot{V}/\dot{Q}$ have a disproportionately greater effect on lowering the arterial saturation than do regions of lung with normal or higher $\dot{V}/\dot{Q}$ to increase P_aO_2. Assuming equal blood flow, the average partial pressure of alveolar oxygen (P_AO_2) of the V/Q regions represented in the illustration is 10.7 kPa (80 mm Hg). Based on the oxyhemoglobin dissociation curve, however, the average saturation of the arterial blood is 89%, producing an average P_aO_2 equal to 7.6 kPa (57 mm Hg). *PO_2*, Partial pressure of oxygen. (Modified from Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier/Butterworth Heinemann; 2005.)

any change in lung gas exchange function. Another limitation is the failure of these indices to account for changes in $\dot{V}/\dot{Q}$ matching resulting from changes in the F_IO_2. In addition, indices that use P_AO_2 rely on the assumptions of the alveolar gas equation, including $P_ACO_2 = P_aCO_2$, which may not hold true in pathologic conditions.

An early index developed to assess oxygenation that used only peripheral blood sampling was the (A-a)PO_2.[188] The (A-a)PO_2 can help to differentiate $\dot{V}/\dot{Q}$ mismatch, shunt, and diffusion limitation from hypoventilation and low F_IO_2 as causes of hypoxemia. This is because the (A-a) PO_2 is unchanged under conditions of decreased F_IO_2 and hypoventilation but increased with $\dot{V}/\dot{Q}$ mismatch, shunt, and diffusion limitation.

The A-a gradient of O_2 is calculated as

$$\text{(A-a) } PO_2 = P_AO_2 - P_aO_2 \qquad (41.19)$$

The normal value of the (A-a)PO_2 is less than 10 mm Hg in young adults breathing room air, and it increases with age and the administration of supplemental O_2. The change in (A-a)PO_2 with age can be estimated by[189]

$$\text{(A-a) } PO_2 = 0.21 \cdot (\text{age} + 2.5) \qquad (41.20)$$

The (A-a)PO_2 varies significantly with the F_IO_2 such that the application of supplemental O_2 can lead to an increase in the (A-a)PO_2 independent of pulmonary disease.[186] Like the (A-a)PO_2, the respiratory index (A-a)PO_2/P_aO_2 and the P_aO_2/P_AO_2 are sensitive to F_IO_2, especially in the presence of a high degree of $\dot{V}/\dot{Q}$ mismatch, such as during acute respiratory distress syndrome (ARDS), and less so in the absence of true shunt or when low $\dot{V}/\dot{Q}$ regions are minimal (e.g., in healthy lung or pulmonary embolus).[190]

Unlike the other indices based on partial pressures, the P_aO_2/F_IO_2 ratio does not use the P_AO_2 and its associated assumptions. This index is more stable, particularly under conditions relevant to ARDS such as P_aO_2 lower than 100 mm Hg in the setting of an F_IO_2 greater than 0.5.[186,187] P_aO_2/F_IO_2 values are part of the diagnostic criteria for ARDS and have been correlated with outcomes in these patients.[191] When repeated arterial blood sampling is not possible, the S_pO_2/F_IO_2 (also referred to as SF) ratio may be useful. SF ratio values have shown good correlation with P_aO_2/F_IO_2 values in both adults and children with respiratory failure who have S_pO_2 values in the range of 80% to 97%.[192,193]

The P_aO_2/F_IO_2 ratio does not characterize factors associated with the severity of respiratory failure such as ventilator settings or respiratory system mechanics.[194-196] Another drawback of the P_aO_2/F_IO_2 ratio is its dependence on PEEP or mean airway pressure, because increases in these variables result in lung recruitment and improved oxygenation. As a consequence, the oxygenation index (OI) was proposed as a more robust alternative to the P_aO_2/F_IO_2 ratio[197]:

$$OI = 100\,\% \times \frac{F_IO_2\bar{P}_{ao}}{P_aO_2} \qquad (41.21)$$

where $\bar{P}_{ao}$ denotes the mean airway pressure. The OI has been used as a prognostic indicator in pediatric patients

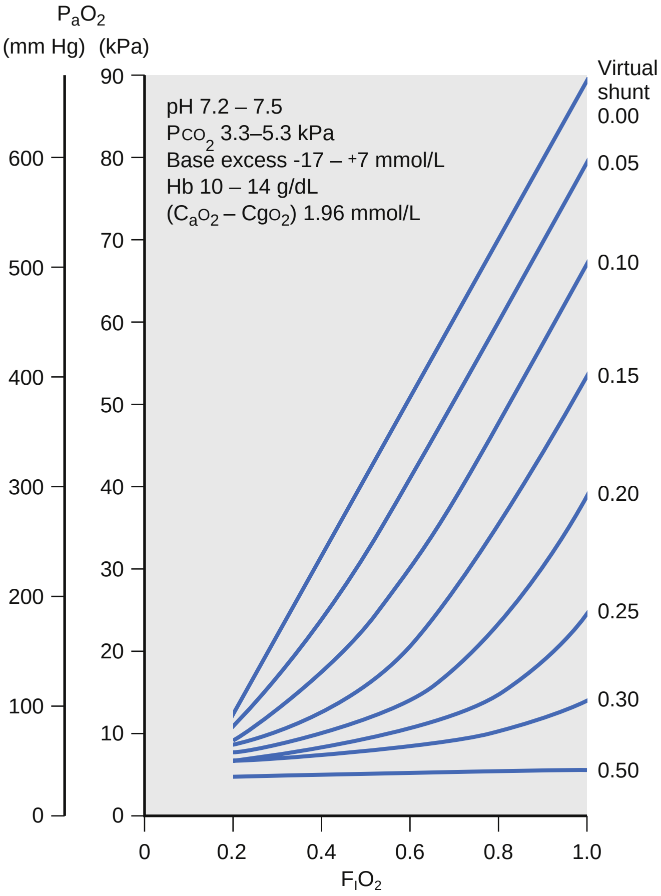

Fig. 41.16 Relationship between partial pressure of arterial oxygen (*P_aO_2*) and fraction of inspired oxygen (*F_IO_2*) for different values of shunt fraction computed for normal values of barometric pressure, pH, partial pressure of carbon dioxide (*PCO_2*), base excess, hemoglobin (*Hb*) concentration, and arterial-mixed venous oxygen content difference (*C_aO_2 – CgO_2*). Note the small increase in P_aO_2 with F_IO_2 in the presence of large shunt. This graph corresponds to the so-called isoshunt diagram presented by Lawler and Nunn. (From Welsby PD, Earis JE. Some high pitched thoughts on chest examination. *Postgrad Med J*. 2001;77:617–620.)

with acute hypoxemic respiratory failure,[198] as a predictor of mortality in adult ARDS,[196,199] and as an index of enhanced lung recruitment during oscillatory ventilation.[200] An alternative "oxygenation saturation index" (OSI) has also been recently proposed:

$$\text{OSI} = 100\,\% \times \frac{F_IO_2\bar{P}_{ao}}{S_pO_2} \qquad (41.22)$$

Similar to the pulse oximetric saturation S_pO_2/F_IO_2 (SF) ratio, the OSI eliminates the need for invasive arterial blood gas sampling by using pulse oximetry. When computed on the day of ARDS diagnosis, it correlates well with the OI and is associated with increased mortality and fewer ventilator free days.[194]

Unlike P_aO_2, P_aCO_2 can be maintained in the normal range in the presence of significant $\dot{V}/\dot{Q}$ mismatching. The reason is that the CO_2 content curve has no plateau. In this way, compensatory hyperventilation can be used to reduce elevations in P_aCO_2.[201] The dependence of P_aCO_2 on CO_2 elimination ($\dot{V}_{CO_2}$) and alveolar ventilation ($\dot{V}_A$), with k in the equation as a conversion factor equal to 0.863, is expressed by

$$P_aCO_2 = k \times \left(\dot{V}_{CO_2}/\dot{V}_A\right) \qquad (41.23)$$

In steady-state conditions (constant $\dot{V}_{CO_2}$), P_aCO_2 changes inversely with the alveolar ventilation. The traditional measure of ventilation inefficiency has been the fraction of dead space to tidal volume (V_D/V_T) as calculated using the Bohr equation (Eq. 41.15) and the assumption that the arterial and alveolar partial pressures of CO_2 are equivalent (i.e., $P_ACO_2 = P_aCO_2$). The dead space fraction determined in this manner includes alveolar (i.e., nonperfused alveoli) and anatomic dead space, as well as regions of high $\dot{V}/\dot{Q}$ ratio. As with the discussion on shunt, the dead space fraction characterizes not only real anatomic dead space, but also areas of inefficient ventilation (see Fig. 41.17).

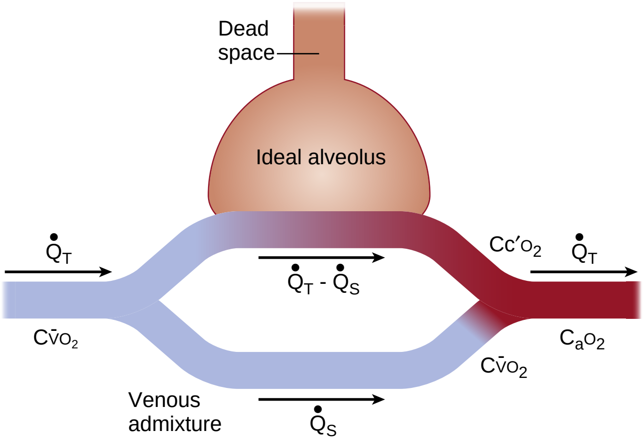

Fig. 41.17 Three-Compartment Model of Gas Exchange. The lung is represented as three functional units: alveolar dead space, "ideal" alveoli, and venous admixture (shunt). Note that the model doesn't differentiate between true shunt or true dead space and components of shunt and dead space that are caused by ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch. *CaO_2*, Arterial oxygen content; *$Cc'O_2$*, oxygen content of end pulmonary capillary blood; $C\bar{v}O_2$, mixed venous oxygen content; $\dot{Q}_S$, shunted blood flow; $\dot{Q}_T$, total blood flow. (From Lumb AB. *Nunn's Applied Respiratory Physiology*. 6th ed. Philadelphia: Elsevier/Butterworth Heinemann; 2005.)

MEASUREMENT PRINCIPLES

P_aO_2 is measured using a Clark electrode. The electrode consists of a cathode (either platinum or gold) and an anode in an electrolytic bath, surrounded by a thin O_2 permeable membrane. The electrode is inserted into the sample, and O_2 diffuses through the membrane and is reduced by the cathode, generating a current. The current is proportional to the PO_2 in the sample.[202] The PCO_2 electrode measures the change in pH brought about by the equilibration of blood with a bicarbonate solution.[203]

Effect of Temperature

The solubility of CO_2 and O_2 in blood is affected by temperature. At lower temperatures, solubility is increased, leading to a reduction in partial pressure. Blood gas analyzers measure gas partial pressures at 37°C. As blood from a hypothermic patient is warmed to 37°C by the analyzer, CO_2 and O_2 will come out of solution, leading to P_aCO_2 and P_aO_2

higher than those present in the patient. Blood gas analyzers make use of algorithms to correct the reported values to the patient's actual temperature.[204] The temperature effects on blood gas analysis are most relevant during management of hypothermic patients, such as during hypothermic cardiopulmonary bypass (HCPB) or deep hypothermic circulatory arrest (DHCA).

Two strategies have been developed for the management of arterial gas partial pressures under these conditions: alpha-stat and pH-stat. During alpha-stat management, blood gas measurements obtained after the analyzer warms the sample to 37°C are used for acid-base and gas exchange management. Potential benefits of alpha-stat management include the preservation of cerebral autoregulation and the maintenance of protein function.[205] During pH-stat management, measurements are corrected to the patient's temperature before they are used for acid-base and gas exchange management. Because patients are hypothermic, the P_aO_2 and P_aCO_2 at the patient's temperature are lower and the pH higher than those measured in the analyzer at 37°C. CO_2 is usually added to the oxygenator to maintain the temperature-corrected P_aCO_2 and pH at normothermic values. The theoretical benefits of pH-stat management are increased cerebral vasodilation leading to more homogenous cerebral cooling.[206]

Studies have compared the two strategies with respect to outcomes with varying results.[207-214] In general, clinical studies support the use of pH-stat management in pediatric cardiac surgical procedures during HCPB or DHCA.[209,213,215] In adult patients, the use of alpha-stat management is supported for HCPB.[216] For procedures involving DHCA in adults, the use of pH-stat management has been suggested to increase the rate and uniformity of cooling and alpha-stat management during rewarming.[217]

LIMITATIONS AND SOURCES OF ERRORS

Proper handling of arterial blood gas samples is important to prevent errors. Two common sources of error are delays in sample analysis and the presence of air in the sampling syringe.[218] A delay in sample analysis by 20 minutes at room temperature or at 4°C can lead to a decline in P_aO_2.[218] The decline is attributed to the metabolic activity of leukocytes and is not observed in samples placed on ice. The presence of an air bubble in the syringe can lead to a change in the measured P_aO_2 toward the PO_2 of the bubble and decline in P_aCO_2.[218]

Monitoring Lung Flows, Volumes, and Pressures:

As an organ of gas exchange, the human respiratory system relies on convective and diffusive gas transport processes for VO_2 and elimination of CO_2. The transport of air to the alveoli and alveolar gas to the environment requires the creation of a pressure gradient, which results in volume changes in the elastic components of the respiratory system, flow in the airways, velocity of moving tissues, and acceleration of air and tissues. The lung consists of a complex branching network of airway segments and viscoelastic tissues that, during the processes of spontaneous breathing or mechanical ventilation, gives rise to tremendous variations in gas velocities and flow regimens. The movement of gas flow ($\dot{V}$) into and out of the lungs requires pressure (P) to overcome the resistive (P_R), elastic (P_E), and at times inertial (P_I) forces offered by the airway tree, parenchymal tissues, and chest wall:

$$P = P_R + P_E + P_I \tag{41.24}$$

Eq. (41.24) can be used to describe the mechanical behavior of the total respiratory system, the lungs alone, or the chest wall, depending on whether P refers to airway pressure relative to atmosphere (transrespiratory pressure), airway pressure relative to pleural pressure (transpulmonary pressure), or pleural pressure alone.[219-221]

DYNAMIC RESPIRATORY MECHANICS

As a first approximation to Eq. (41.24), the mechanical behavior of the respiratory system during breathing or ventilation can be described according to the simple equation of motion that encompasses its resistive (R), elastic (E), and inertial (I) properties[219,222]:

$$P = R\dot{V} + EV + I\ddot{V} + P_o \tag{41.25}$$

where V is volume, $\ddot{V}$ denotes volume acceleration (i.e., the first time-derivative of flow or the second time-derivative of volume), and P_o is the distending pressure at end expiration. The coefficients R, E, and I in Eq. (41.25) may refer to the mechanical properties of the total respiratory system (rs), the lungs alone (L), or the chest wall (cw), depending on whether P refers to transrespiratory pressure, transpulmonary pressure, or intrapleural pressure, respectively.[221] The resistive properties of the respiratory system (R_{rs}) are generally assumed to arise from viscous and turbulent losses associated with gas flowing through the airway tree and the deformation of parenchymal and chest wall tissues. Hence, airway resistance may reflect airway caliber.[223] Provided that variations in flow are small, resistive pressure losses are assumed to be linearly related to flow according to the first term of Eq. (41.25). With more rapid flow rates, as may be seen during exercise or forced vital capacity maneuvers, resistive losses vary nonlinearly with flow, which may more accurately be described according to[224]

$$P_R = K_1\dot{V} + K_2\dot{V}^2 \tag{41.26}$$

where K_1 and K_2 are empirically determined constants. Additional energy losses arise from the tension within the alveolar surface film,[225] friction within the pleural space, and various tissue components of the parenchyma and chest wall,[220] as well as cross-bridge cycling of contractile elements within the airway walls and lung tissues.[226,227] Such losses are collectively termed "tissue resistance."[228,229] If these tissue resistive losses are assumed to be proportional to flow according to Eq. (41.25), one will observe that they vary inversely with breathing frequency,[226,230] a phenomenon commonly associated with viscoelastic materials.[220] In adult patients, lung tissue resistance comprises about 60% of subglottal total lung resistance at typical breathing rates.[231] During volume-cycled ventilation with an end-inspiratory pause, resistance can quickly be estimated from the difference between the peak (P_{peak}) and plateau (P_{plat}) airway pressures (i.e., the resistive pressure loss P_R) divided

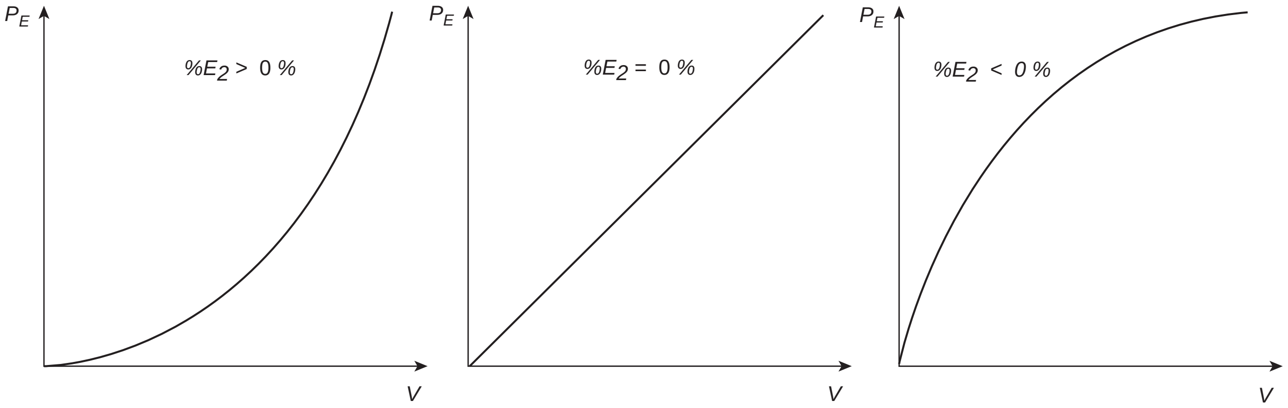

Fig. 41.18 Example elastic pressure *(P_E)* versus volume *(V)* curves and corresponding percentage of volume-dependent respiratory system elastance *($\%E_2$)* values. (Modified from D'Antini D, Huhle R, Herrmann J, et al. Respiratory system mechanics during low versus high positive end-expiratory pressure in open abdominal surgery: a substudy of PROVHILO randomized controlled trial. *Anesth Analg.* 2018;126:143–149.)

by the inspiratory flow ($\dot{V}_I$) immediately before the end-inspiratory pause:

$$R = \frac{P_{peak} - P_{plat}}{\dot{V}_I} = \frac{P_R}{\dot{V}_I} \qquad (41.27)$$

Thus, for a specified flow rate, alterations in P_R may reflect changes in airway caliber, as may occur during an intraoperative asthma exacerbation (Fig. 41.18, center panel), or obstruction within the ETT or breathing circuit.

Elastic pressures arise from the recoil of the lungs and chest wall when their normal anatomic configurations are deformed, either by contraction of the diaphragm and intercostal muscles, or by some external force such as a ventilator.[232] Elastance is defined as the change in distending pressure (transrespiratory, transpulmonary, or intrapleural) for a given change in volume. *Dynamic elastance* refers to the change in elastic (i.e., nonresistive) distending pressure per unit volume during the process of breathing or ventilation.[†]Elastance of the total respiratory system (E_{rs}) comprises both lung (E_L) and chest wall (E_{cw}) elastances:

$$E_{rs} = E_L + E_{cw} \qquad (41.28)$$

In clinical settings, elastance is usually expressed as its reciprocal, compliance (i.e., change in volume per unit change in pressure). This leads to an alternate form of Eq. (41.28), expressing the relationships of the compliant components of the total respiratory system (C_{rs}), lungs (C_L), and chest wall (C_{cw}):

$$\frac{1}{C_{rs}} = \frac{1}{C_L} + \frac{1}{C_{cw}} \qquad (41.29)$$

Factors that increase total respiratory or lung elastance (or likewise reduce the corresponding total respiratory or lung compliance) include consolidation, pulmonary edema, pneumothorax, atelectasis, interstitial disease, pneumonectomy or surgical resection, lung overdistension, and mainstem intubation. Lung compliance generally increases in emphysema. Factors that reduce chest wall compliance are abdominal distension, abdominal compartment syndrome, chest wall edema, thoracic deformity, muscle tone, and extensive thoracic or abdominal scar (e.g., from burns); C_{cw} is reduced with muscle relaxation and flail chest.

In some situations, the magnitude of V_T, relative to the functional lung size, may be such that the linear dependence of P_E on V (Eq. [41.24] and [41.25]) is no longer an accurate description of the pressure-volume (PV) relationship of the lungs and/or chest wall. In these cases, elastic pressure may be more accurately described by a quadratic relationship with volume[232a,232b]:

$$P_E = E_1 V + E_2 V^2 \qquad (41.30)$$

in which E_1 and E_2 denote the so-called volume-independent and volume-dependent components of elastance, respectively, since P_E will be reduced to E_1V when E_2 is negligible (Eq. [41.23]). An advantage of using Equation 41.30 is that it readily allows for the determination of the percentage of volume-dependent elastance contributing to P_E[232c]:

$$\%\,E_2 = \frac{E_2 V_T}{E_1 + E_2 V_T} \times 100\,\% \qquad (41.31)$$

Since the $\%E_2$ index quantifies the deviation of linearity between P_E and V, it may provide quantitative information on the degree of intratidal recruitment or overdistention occurring during a mechanical breath.[232d] For example, positive values of $\%E_2$ (see Fig. 41.18*A*) indicate a convex P_E-V relationship, with probable overdistention occurring for $\%E_2$ greater than 30%.[232c] By contrast, negative values of $\%E_2$ (see Fig. 41.18*C*) indicate concave P_E-V relationship, with likely intratidal recruitment occurring during the breath.[232e]

For the special case of constant inspiratory flow during volume-cycled ventilation, the curvature of the inspiratory pressure-time profile can also be used to infer the processes of intratidal recruitment and overdistention. Raneiri and associates[232f] described this relationship using a simple power law expression:

$$P = at^b + c \qquad (41.32)$$

where, similar to Eq. (41.24), P may refer to either transrespiratory or transpulmonary pressure, and t is time. The constants a, b, and c can be estimated from the inspiratory pressure profile using various nonlinear regression techniques.[232g] The exponent b is referred to as the "stress

---

[†] Certain conventions of nomenclature incorrectly define dynamic elastance as the *peak* airway pressure divided by tidal volume. However, such a definition of dynamic elastance includes both resistive *and* elastic pressures, and thus is not an index of purely elastic processes.

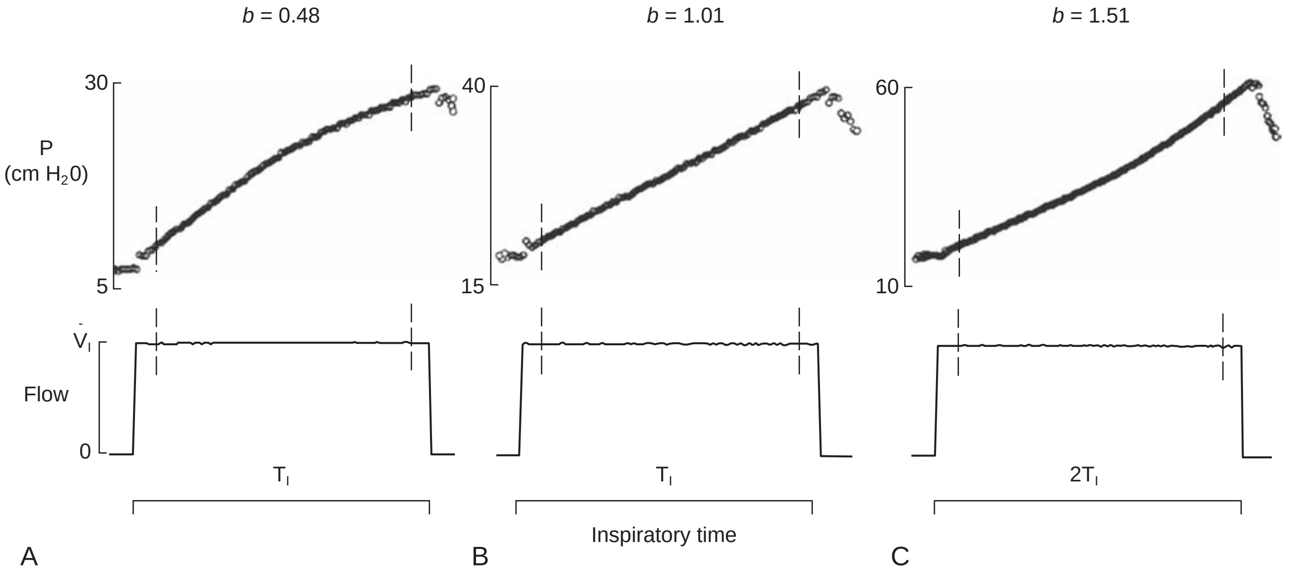

Fig. 41.19 Conceptual example of the stress index during constant inspiratory flow levels of $\dot{V}_I$ over durations of T_I and $2T_I$, assuming that the power law $P = at^b + c$ can describe the pressure-time (P-t) curve. (A) b <1.0, yielding a convex P-t curve, suggesting the dominance of intratidal recruitment; (B) b ~ 1.0, yielding a straight P-t line, suggesting minimal recruitment or overdistension; and (C) b >1.0, yielding a concave P-t curve, suggesting the dominance of parenchymal overdistension. (Modified from Ranieri VM, Zhang H, Mascia L, et al. Pressure-time curve predicts minimally injurious ventilatory strategy in an isolated rat lung model. *Anesthesiology.* 2000:93:1320–1328.)

index," and its estimated value characterizes the convexity (b <1.0), concavity (b >1.0), or linearity (b = 1.0) of the inspiratory pressure with time (Fig. 41.19). Similar to %E_2, b may also provide some insight into the relative contributions of intratidal recruitment (b <1.0) and parenchymal overdistention (b >1.0) to inspiratory pressure, or when these processes may be appropriately balanced (b ~ 1). However, as noted, the stress index is only interpretable during volume-cycled with constant inspiratory flows, in contrast to the %E_2 index, which can be used during other ventilatory modalities.[232h] Moreover, the interpretation of the stress index may be obscured during certain clinical situations, such as abdominal insufflation, abdominal compartment syndrome, or pleural effusion.[232i,j,k]

Similar to Eq. (41.27) to estimate R_{rs}, linear approximations to respiratory system elastance (E_{rs}) can be easily determined during volume-cycled ventilation for periods of zero-flow (i.e., during an end-inspiratory pause, when resistive pressures are zero) as the difference between P_{plat} and PEEP (i.e., the elastic pressure P_E) divided by the V_T:

$$E_{rs} = \frac{P_{plat} - PEEP}{V_T} = \frac{P_E}{V_T} \qquad (41.33)$$

Since the value of E_{rs} in Eq. (41.33) is obtained during zero-flow, it is often referred to as "static elastance." The corresponding static C_{rs} is usually between 50 and 100 mL/cm H_2O in normal mechanically ventilated lungs. Alterations in P_E for a specified V_T may be observed during processes that alter lung or chest wall elastance, such as a pneumothorax during thoracotomy or abdominal insufflation during laparoscopic surgical procedures (Fig. 41.20, *right panel*). In contrast to static E_{rs}, dynamic E_{rs} is estimated during periods of nonzero-flow by using multiple linear regression techniques (see later), and is higher than static elastance because of viscoelasticity[222] and gas redistribution.[233] Both the apparent static or dynamic E_{rs} will decrease following a recruitment maneuver because of an increase in aerated or functional lung volume. However, E_{rs} may also be increased due to *strain stiffening* of the lung tissues,[233a] in which collagen fibers within the extracellular matrix of the parenchyma become progressively recruited with increasing strain. Recruitment of stiff collagen fibers results in their dominance of load-bearing within the lung, in contrast to the more stretchable elastin fibers that are the main load-bearing elements during low levels of tissue strain.[233b] Such behavior may allow for titration of PEEP to achieve an optimal balance between intratidal recruitment and parenchymal overdistention—that is, the PEEP for which E_{rs} is minimized or, equivalently, C_{rs} is maximized.[232b,c,233c-f] The clinical utility of such PEEP titration in patients with ARDS is still not entirely established.[233e,233g]

Finally, inertial pressures are associated with the kinetic energy of accelerating the gas column in the central airways, as well as the motion of the respiratory tissues.[234] Inertial pressures are typically expressed as the product of a lumped "inertia" parameter and volume acceleration (Eq. [41.25]). Inertia is usually not a significant contributor to the apparent airway pressure or the work of breathing, except during sudden changes in air flow, as may occur during inspiratory step profiles or various modalities of high-frequency ventilation (HFV).[235,235a,b]

Eqs. (41.27) and (41.33) cannot be used to estimate R_{rs} and E_{rs} if an end-inspiratory pause is not present in the ventilator waveform. This is because one cannot easily separate the resistive and elastic pressures by visual inspection alone. For example, during pressure-controlled ventilation (PCV), the airway opening is exposed to a constant inflation pressure during inspiration (Fig. 41.21). Airway flow and V_T during PCV are determined not by the ventilator, but rather by the gradient between airway and alveolar pressures. Thus a more robust method of estimating respiratory

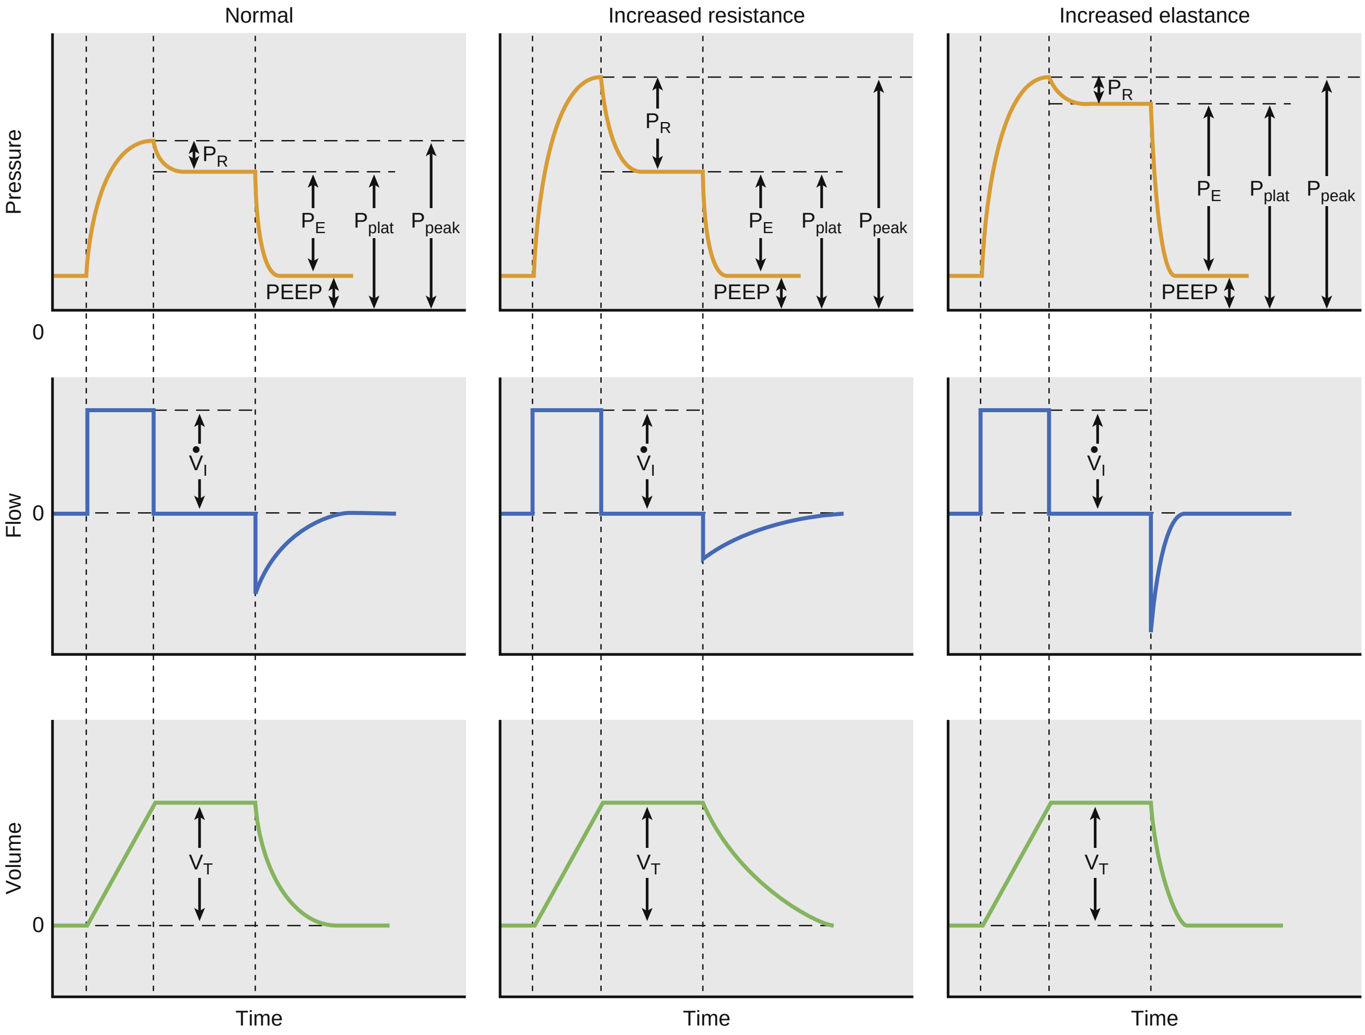

Fig. 41.20 Airway pressure, flow, and volume waveforms during constant-flow volume-cycled ventilation with an end-inspiratory pause. The components of the peak inspiratory pressure *(P_{peak})* and the plateau pressure *(P_{plat})* are presented: *P_R*, resistive pressure; *P_E*, elastic pressure; and *PEEP*, positive end-expiratory pressure. The same peak flow ($\dot{V}_I$) and tidal volume *(V_T)* are delivered by the mechanical ventilator in each case. Leftmost panels represent waveforms in a healthy patient. There is a small resistive pressure component, with most of the peak pressure comprised of elastic pressure. Expiratory flow decreases to zero before the start of the next inspiration, indicating appropriate I:E ratio and the absence of slowly emptying lung regions. Volume, as the integral of flow, also returns to zero before the initiation of the next breath. Middle panels represent waveforms in a patient with an increase in airways resistance. There is a significant increase in the resistive component P_R, and consequently P_{peak}. The elastic component is unchanged, as reflected in identical P_{plat} as compared with the healthy condition. Because increased resistance slows the process of lung emptying, the expiratory phase of the flow and volume curves now take longer to reach the zero. In several cases, the zero will not be reached, and a change in the I:E ratio will be necessary to avoid volume trapping and auto-PEEP. Rightmost panels represent a subject with increased P_E, as may occur during laparoscopic insufflation or pneumothorax. There is an increase in P_{plat} consistent with the increased elastance of the respiratory system, and a fast emptying of the lungs during exhalation.

R_{rs} and E_{rs} involves multiple linear regression of the coefficients in Eq. (41.25) on sampled flow and pressure data.[236-238] Such numerical approaches are present in commercially available respiratory mechanics monitors, and they can be used on almost all ventilator waveforms. Moreover, estimates of mechanical properties based on linear regression are not restricted to volume- or time-cycled waveforms with an end-inspiratory pause. One can separately estimate R_{rs} and E_{rs} during the inspiratory and expiratory phases, which may be different in some patients because of dynamic airway compression or derecruitment.[239,240]

Dynamic estimates of total respiratory R_{rs} and E_{rs} based on positive airway opening pressures are valid only during controlled modes of ventilation when the chest wall is relaxed. Although this is certainly the case during general anesthesia with neuromuscular blockade, the situation is more complicated during spontaneous breathing or assisted modes of ventilation. In such situations, the mechanics of the chest wall can be accounted for, if transpulmonary pressure is estimated using esophageal manometry, as described later.

STATIC RESPIRATORY MECHANICS

As previously illustrated, elastance (or compliance) is most easily measured during periods of zero flow because during these conditions the measured distending pressure is exclusively associated with elastic processes. However, a

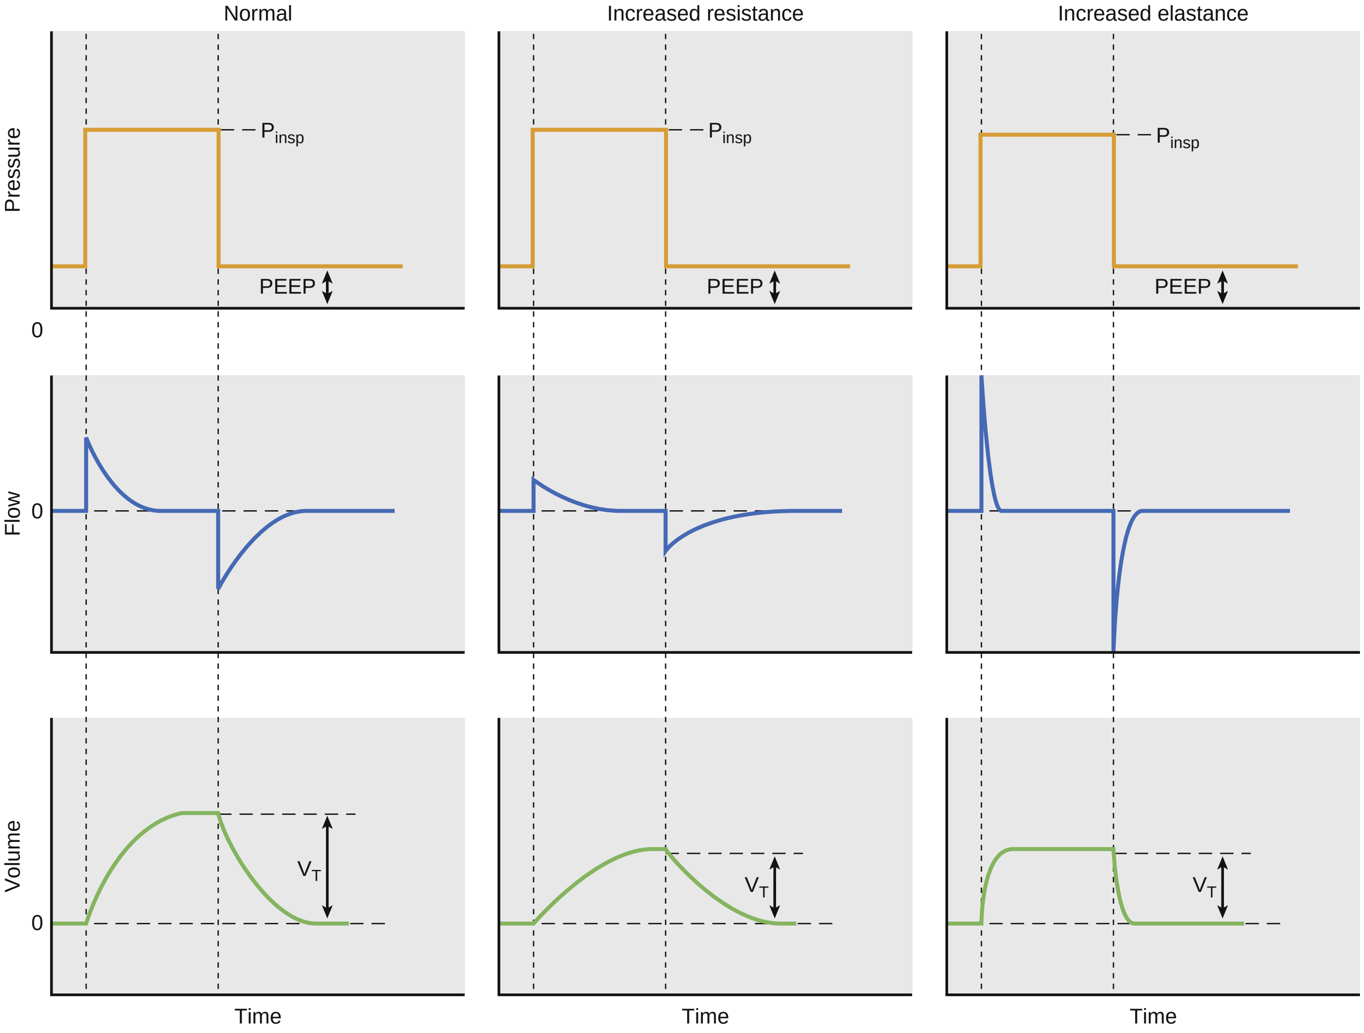

Fig. 41.21 Airway pressure, flow, and volume waveforms during pressure-controlled ventilation for the same patients depicted in Fig. 41.18. In this ventilatory mode, the ventilator delivers a fixed pressure during the inspiratory phase, irrespective of the resistance and compliance. Airflow and tidal volume will consequently change with changes in those parameters. Leftmost panels represent waveforms in a patient with normal lungs. Middle panels represent waveforms in a patient with airway obstruction. Note the absence of a peak-plateau difference as compared with the volume-controlled mode, a lower V_T, and a prolonged time for airflow to reach zero during exhalation as compared to the normal patient. Rightmost panels represent a subject with increased elastance, as may occur during laparoscopic insufflation or pneumothorax. Note a reduction in V_T and a shorter time to reach zero flow consistent with a more rigid lung. *PEEP,* positive end-expiratory pressure; P_{insp}, inspiratory pressure; V_T, tidal volume.

more comprehensive characterization of elastance can be obtained by plotting cumulative inspired or expired lung volume against the distending pressure across the lungs or total respiratory system. This quasi-static PV curve can be constructed during very slow inflations or deflations[241] (when resistive pressures are negligible), or during periodic flow occlusions.[242] For example, the expiratory limb of the PV curve can be constructed by inflating the lungs to a specified volume (usually total lung capacity) and then allowing a passive deflation with flow interruptions of 1 to 2 seconds.

The quasi-static PV curves of the lungs or total respiratory system are inherently nonlinear (Fig. 41.22); that is, compliance, defined as the local slope (dP/dV) of the PV curve, varies with lung volume. Empirically, PV curves are described using single exponential[243] or sigmoidal[244] functions. When they are described using sigmoidal functions, two points are usually demarcated on such curves, which have traditionally been termed the upper inflection point (UIP) and lower inflection point (LIP)[‡] The UIP is thought to represent the point at which lung overdistention occurs, as during parenchymal strain-stiffening,[220] The LIP is thought to reflect the process of maximum alveolar recruitment. During protective ventilation, one seeks to ventilate a patient in the most linear region of the PV curve.

Enough PEEP needs to be applied to avoid the LIP, where cyclic recruitment and derecruitment occur, along with lower V_Ts to avoid the UIP and overdistention.[242] Also, PV curves exhibit hysteresis, a phenomenon in which the lung volume at a specified pressure depends on the direction from which the distending pressure is approached (i.e., either inspiration or expiration). The reasons that the PV curve of the lungs or total respiratory system exhibits hysteresis are numerous and complex, and include the biophysical

---

[‡] The formal mathematical definition of an inflection point is a point on a curve at which its concavity (i.e., its second derivative) changes sign from positive to negative or vice versa.

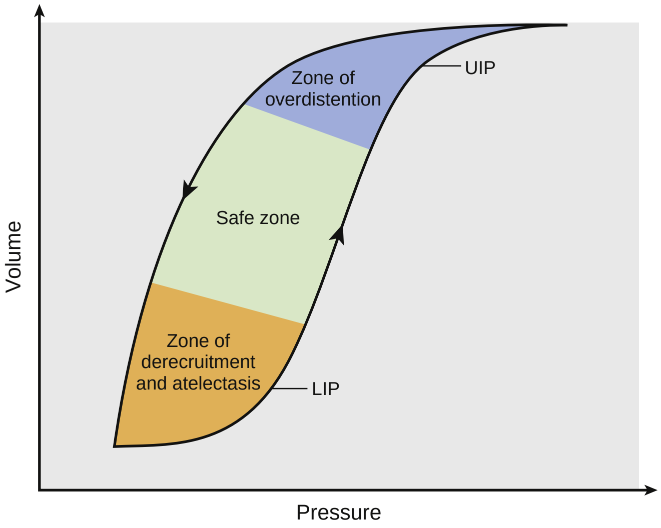

Fig. 41.22 Schematic of a pressure–volume curve for the lungs or total respiratory system, demonstrating hysteresis between inspiratory and expiratory limbs. Upper inflection point *(UIP)* and lower inflection point *(LIP)* are demarcated on the inspiratory limb. During mechanical ventilation, lung regions should be in the Safe Zone for optimal lung protection.

properties of surfactant,[245] time-dependent recruitment or derecruitment,[246] as well as contact friction among various connective tissue elements.[247]

There are a number of problems with managing ventilation based on quasi-static PV curves. First, PV curves are constructed only during periods of zero flow or near zero flow, and they do not reflect the mechanics of the lungs or total respiratory system during the dynamic processes of breathing or mechanical ventilation. In fact, the dynamic PV relationships for the same patient may be very different. Second, the UIP and LIP are not always visually apparent. Finally, a PV curve for the lungs or total respiratory system represents the averaged static behavior of a population of many lung units, with each operating on different portions of their own individual PV curves.

WORK OF BREATHING AND MECHANICAL POWER

The work of breathing (W) represents the energy required to inflate or deflate the lungs, or chest wall, or both, by a specified volume. In its simplest form, it can be represented as the product of the applied distending pressure and resulting volume change:

$$W = PV \qquad (41.34)$$

However, when pressure and volume vary as functions of time (as during the course of a spontaneous or controlled breath), work may be expressed as the cumulative product[248]

$$W = \int PdV \qquad (41.35)$$

or equivalently as the integral of the pressure-flow product with respect to time[249]

$$W = \int_{t=0}^{T} P(t)\,\dot{V}(t)\,dt \qquad (41.36)$$

where T is the duration over which W is determined. For example, if T corresponds to the duration of inspiratory period and P the transpulmonary pressure, then W corresponds to the work required to overcome both the resistive and elastic forces opposing the entry of air into the lungs (Fig. 41.23). If T corresponds to the duration of an entire breath, the energy initially stored in the elastic recoil of the lung tissues will be recovered during a passive exhalation. In this case, the area of the resulting PV loop represents the work performed (i.e., energy lost) overcoming purely resistive losses in the airways and tissues. In general, W is assessed during inspiration only because the respiratory musculature (or a ventilator) must overcome both elastic and resistive pressures to bring air into the lungs. For a given V_T, W varies as a function of respiratory rate and, in most cases, achieves a minimum at a specified frequency. This frequency is termed the *energetically optimum breathing frequency*,[249] as this is the rate at which energy expenditure is minimized. The derivative of W with respect to time is referred to as the *instantaneous mechanical power*, P,

$$P = \frac{dW}{dt} \qquad (41.37)$$

which, based on Eq. (41.31), can simply be expressed as the pressure-flow product with respect to time:

$$P(t) = P(t)\,\dot{V}(t) \qquad (41.38)$$

Mechanical power, as an index of the *rate* of energy dissipation, can be used to assess the risk of developing ventilator-induced lung injury,[249a] particularly with changes in transpulmonary pressure during ventilation.[249b] Moreover, if the relationship between pressure and flow during ventilation can be described by relatively simple mathematical expressions (e.g., Eqs. [41.25]–[41.27]), the mechanical power likewise can be embodied by simple analytic formulæ.[249c,d]

MONITORING OF RESPIRATORY PRESSURES

Fundamental to any quantitative assessment of respiratory mechanics is the measurement of pressure. Such pressures may include those measured in the inspiratory or expiratory limb of the anesthesia machine, at the proximal end of an ETT, or within the trachea or esophagus. Pressure allows for the inference of the forces associated with the movement of gases through the airway tree, as well as the distension of the parenchymal tissues and chest wall, according to the elements described in Eq. (41.24). The most accessible and familiar pressure to the anesthesiologist or intensivist is the airway pressure during controlled mechanical ventilation. Ideally, this should be the pressure measured in the trachea or at the airway opening, exclusive of any distortions from airway devices or breathing circuits. However, for practical reasons, this “airway” pressure is not the actual pressure at the airway opening or within the trachea, but is the pressure transduced at the anesthesia machine or ventilator and reflects the resistive and compliant properties of the breathing circuit and face mask or ETT, as well as the mechanical properties of the respiratory system. Although many ventilators now use computer algorithms to provide some compensation for flow and pressure losses in the breathing circuit,[250] such approaches often rely on idealized, linear models that do not truly reflect the complex

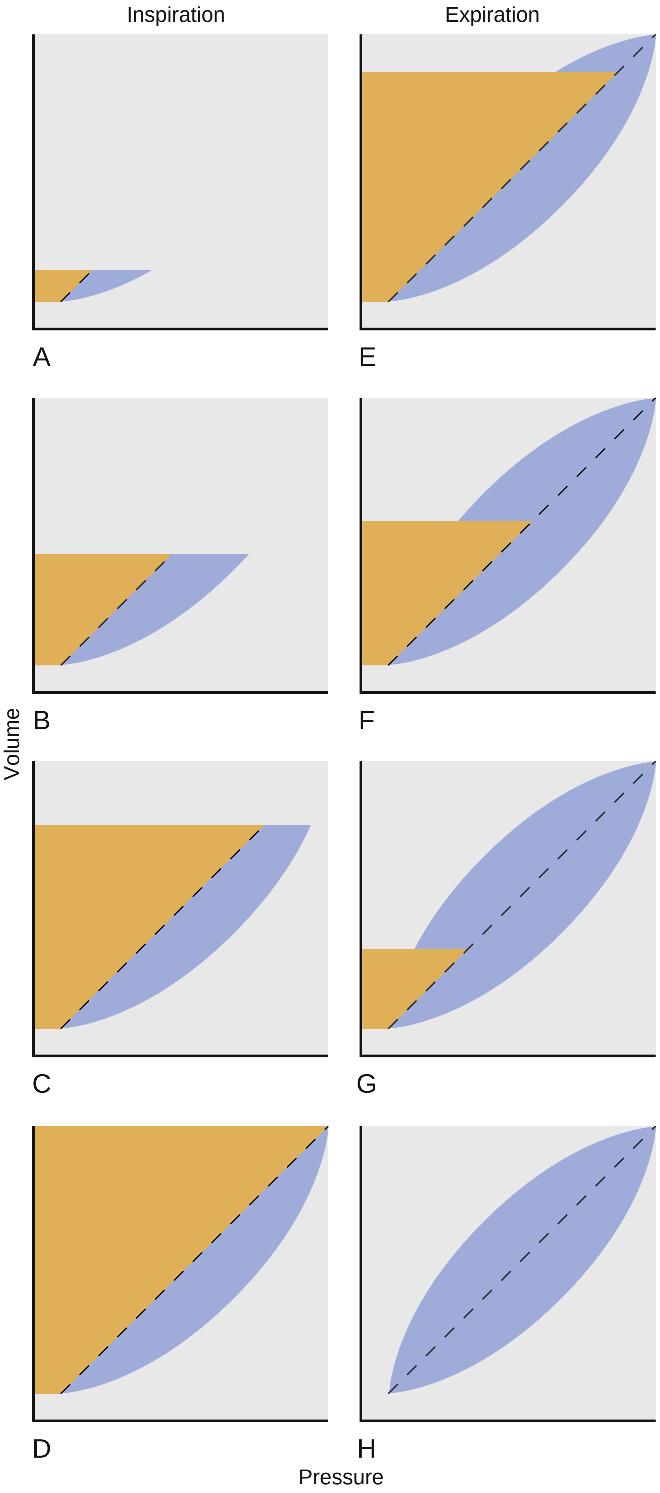

Fig. 41.23 Volume plotted against transpulmonary or (transrespiratory) pressure during the course of a single breath. Plots are shown during inspiration (panels A through D) and expiration (panels E through H). *Gray area* denotes the work of breathing due to tissue elasticity, while the *hatched area* denotes the work of breathing due to airways and tissue resistance. Energy stored in elastic recoil at the end of inspiration will be entirely recovered during expiration. However, resistive energy will always be lost during both inspiration and expiration.

processes of turbulent air flow, polytropic gas compression, or viscoelastic tubing walls.[251,252] Therefore, one must use caution when making physiologic inferences based on airway pressures and volumes reported by a ventilator.

Often airway pressure is improperly used as a surrogate for lung distention. *Transrespiratory pressure* refers to the pressure drop across the lungs and chest wall, which during positive-pressure ventilation is usually determined by the difference between airway pressure and atmospheric pressure. Several processes that may contribute to increased transrespiratory pressure do not correspond to excessive lung inflation. For example, obesity, abdominal insufflation, or steep Trendelenburg position all may contribute to high airway opening pressures, but they do not necessarily indicate parenchymal overdistention.

By contrast, *transpulmonary pressure* refers to the distending pressure across the lungs alone. Its determination requires not only measurement of airway opening pressure, but also estimates of the pressure within the pleural space. This can be obtained relatively noninvasively using an esophageal balloon catheter, because the pressure measured within the esophagus is relatively close to intrapleural pressure.[253,253a] Such catheters are typically 100 cm long, with side holes in the distal tip covered by a thin-walled balloon (Fig. 41.24). The catheter can be placed through the mouth or nares and positioned in the middle-to-distal third of the esophagus. The catheter is connected to a transducer by a three-way stopcock, and a small amount of air is injected into the balloon such that its walls remain flaccid and do not contribute an additional recoil pressure to the measurement. Because the local values of pleural pressure vary depending on gravity, the balloon should be several centimeters in length to provide an average estimate of the pressure field surrounding the lungs. Estimating pleural pressure based on esophageal manometry has several limitations, including mediastinal compression of the balloon in supine patients, catheter migration, and cardiac artifact on the tracing.[254,255] Nonetheless, its use in critically ill patients and under certain special conditions such as obesity, abdominal hypertension (primary or during laparoscopic insufflation), and extreme Trendelenburg position may be valuable in the adjustment of appropriate levels of PEEP.[256,256a] Peak and plateau pressures, which are typical in clinical practice, are obtained from the *transrespiratory* pressure. Accordingly, they do not characterize the pressures acting exclusively on the lungs, but on the whole respiratory system. Current recommendations suggest limiting transrespiratory plateau pressures to 26 to 30 cm H_2O, to minimize alveolar overdistension.[257] However, such recommendations should be applied in appropriate clinical context, given that the same plateau pressure could correspond to very different transpulmonary pressures, and consequently to very different degrees of risk for lung injury, depending on the partitioning between lung and chest wall pressure components.[257a,b]

More recent studies suggest that the “driving pressure”—that is, the V_T normalized by the respiratory system compliance ($\Delta P = V_T/C_{rs}$)—may be one of the most important ventilatory variables to consider when stratifying mortality risk during ARDS.[257c,d] Its relationship to postoperative pulmonary complications in surgical patients has also been demonstrated.[258,259] In practice, driving pressure may be computed as the difference between P_{plat} and PEEP.[257c]

Auto-PEEP or *intrinsic-PEEP* is the positive pressure present within the alveoli at end-exhalation and is typically observed in ventilated patients with COPD, who demonstrate dynamic airway compression and expiratory flow limitation, as well as a significant portion of patients with ARDS, sepsis, and respiratory muscle weakness.[260] Auto-PEEP can promote significant respiratory and hemodynamic compromise. It is usually caused by a combination of increased airway resistance and reduced lung elastic recoil (i.e., an increase in the expiratory time constant of the respiratory system). Other factors are a decrease in expiratory time, an increase in V_T, an increase in external expiratory resistance, and persistent inspiratory muscle activity during exhalation. The amount of auto-PEEP can be estimated in mechanically ventilated patients by occluding the airway at end exhalation, and observing a rise in airway pressure during the occlusion maneuver until a plateau is visible (<4 seconds) (Fig. 41.25). Auto-PEEP is then defined as the difference between end-occlusion to preocclusion airway pressures. Other methods can be used to assess auto-PEEP under dynamic conditions, as well as in spontaneously breathing patients with the use of an esophageal balloon.[260,261]

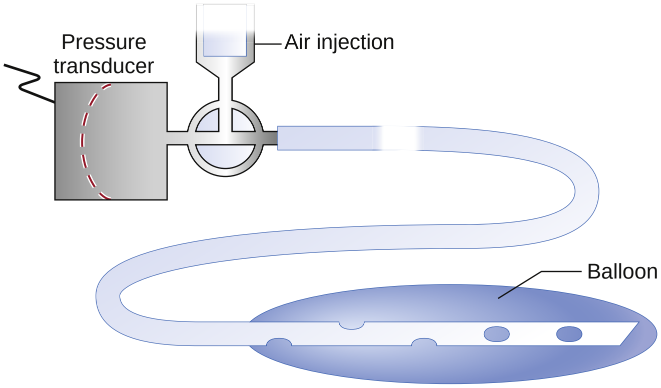

Fig. 41.24 Example of an Esophageal Balloon Catheter. The proximal end of the catheter is connected to a pressure transducer, and air is injected into the balloon via a three-way stopcock. (Modified from Bates JHT. *Lung Mechanics: an Inverse Modeling Approach*. Cambridge: Cambridge University Press; 2009:220.)

Any measurement of pressure requires pressure transducers. Most pressure transducers are differential sensors with two input channels, and they produce an electrical output that is proportional to the pressure difference between these channels (Fig. 41.26*A*). Such transducers exhibit a high common-mode rejection ratio, defined as the tendency of the transducer to produce zero output if both of its inputs are exposed to identical pressures. Many pressure waveforms are transduced relative to atmosphere with one of the two inputs left opened to ambient air (see Fig. 41.26*B*), otherwise referred to as gauge configuration. In clinical settings, pressure is most commonly measured using relatively inexpensive, piezoresistive transducers.[222] These devices rely on a pressure-sensing diaphragm

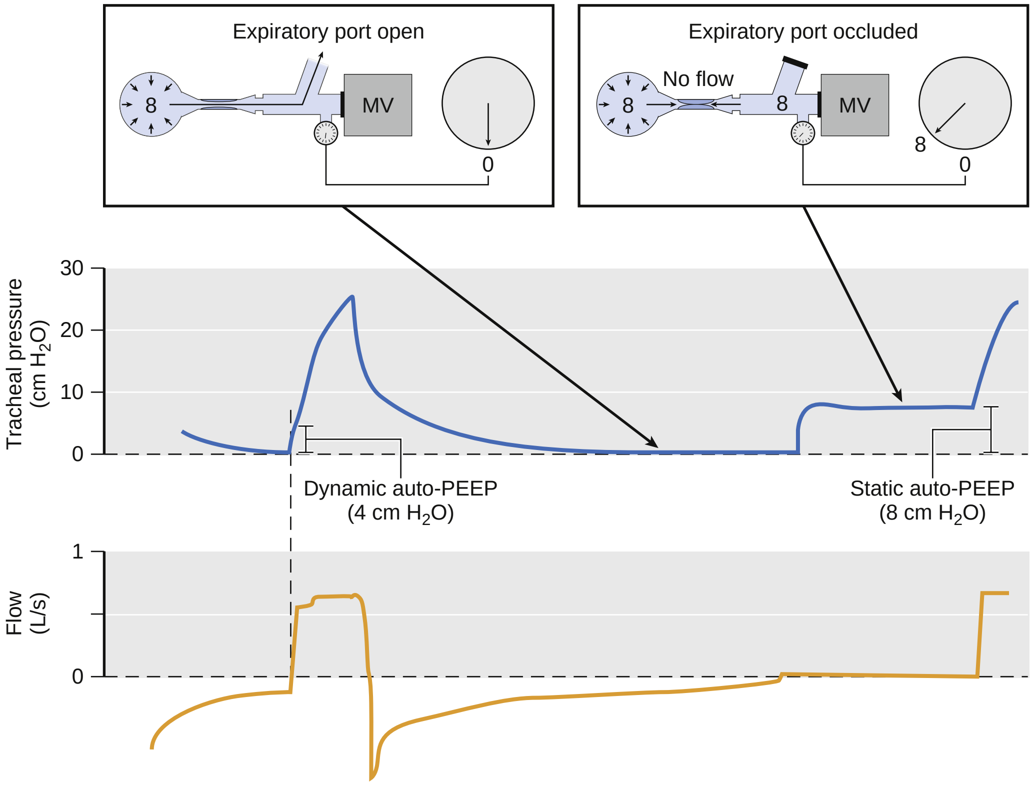

Fig. 41.25 Concept of Intrinsic Positive End-Expiratory Pressure (auto-PEEP). Shown are tracheal pressure and flow waveforms during controlled mechanical ventilation. Dynamic auto-PEEP can be estimated at the beginning of inspiration as the tracheal pressure when the flow trace equals zero. Static auto-PEEP can be estimated as the tracheal pressure following a prolonged expiratory occlusion. (Modified from Blanch L, Bernabé F, Lucangelo U. Measurement of air trapping, intrinsic positive end-expiratory pressure, and dynamic hyperinflation in mechanically ventilated patients. *Respir Care*. 2005;50:110–123; and Moon RE, Camporesi EM. Respiratory monitoring. In: Miller RD, Fleisher LA, Johns RA, eds. *Miller's Anesthesia*. 6th ed. New York, NY: Churchill Livingstone; 2005:1255, 1295.)

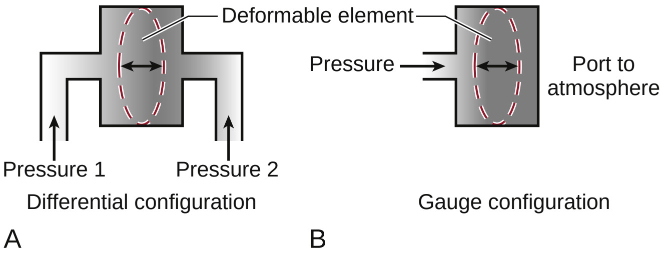

Fig. 41.26 Pressure transducers arranged in differential (A) or gauge (B) configurations. (Modified from Bates JHT. *Lung Mechanics: An Inverse Modeling Approach*. Cambridge: Cambridge University Press; 2009:220.)

whose electrical resistance changes when it is deformed in response to a differential pressure. This change in electrical resistance can be sensed with a standard Wheatstone bridge circuit, which produces an output-voltage signal appropriate for amplification and filtering. In general, piezoresistive transducers have adequate frequency responses sufficient for most respiratory applications.[262,263] However, this frequency response can be easily degraded if the transducer is connected to the pressure-sensing location with long, compliant tubing.[264]

MONITORING OF RESPIRATORY FLOWS

Ideally, any measurement of flow should indicate the exact rate at which gas is entering and leaving the patient's lungs. This can be most easily accomplished by placing the flow-measuring device as close to the patient as possible, such as between the circuit Y-connector and the proximal end of the ETT or LMA. However, for practical reasons, most ventilators and anesthesia machines measure flow close to the machine console. This flow can be considerably different from that close to the patient because of the effects of gas compression, wall distention of the breathing circuit, and changes in gas humidity.

An important clinical use of flow monitoring is the detection of nonzero end-expiratory flows. This indicates that a gradient of pressure exists between alveolar regions and the upper airway with incomplete lung emptying at end-expiration, characteristic of auto-PEEP (PVolFl-7). As a consequence, end-expiratory lung volumes would be larger than those in the absence of auto-PEEP, with risk of dynamic lung hyperinflation and reduction of venous return. Increase in expiratory time and reduction of V_T or respiratory rate should be considered to eliminate the issue.

During ventilation, airway flow can often be inferred according to time-dependent changes in delivered or inspired V_T or from the displacement waveform of a piston or cylinder arrangement or bellows.[265-267] Preferably, flow is measured using transducers designed specifically for this task. The most common method involves the measurement of a differential pressure decrease (ΔP) across a fluid resistive element. Ideally, this ΔP is linearly related to the corresponding flow through the device. Such a principle forms the basis for one of the oldest and most widely used flowmeters, the pneumotachograph. Although the instruments provide accurate measurement of flow, pneumotachographs are very sensitive to changes in temperature, humidity, and gas composition,[268] and require frequent calibration using various electronic or software-based techniques to ensure accurate measurements.[269,270] This sensitivity, combined with difficulties in cleaning and sterilization, limits the routine use of these instruments in clinical environments. Orifice flowmeters also have the advantage of having relatively large internal diameters that limit the formation of condensation and minimize obstruction with secretions. Given that these devices can be manufactured using inexpensive plastic injection molding techniques, many orifice flowmeters are designed to be disposable, thus making their use increasingly popular for respiratory applications in clinical environments.[271]

Most anesthesia machines use hot wire anemometers for flow measurement,[272] which rely on temperature-dependent changes in the electrical resistance of a current carrying wire. When gas flows past the wire, the corresponding temperature drop changes the conductivity of the filament, which can be sensed with appropriate electronic circuits.[273] Because a single wire filament cannot sense the direction of flow, two different anemometers can be used in the ventilator circuit: one for the inspiratory limb, and the other for the expiratory limb. Alternatively, two wires in series must be used for sensing bidirectional flow through a single conduit,[274] with the flow direction determined according to which wire is cooled first. In general, hot wire anemometers have a better dynamic response compared with pneumotachographs or orifice flowmeters,[275] making them ideal for flow measurement during HFV.[235a,276] However, these devices must also be calibrated to account for variations in gas density or humidity as well.[276a]

MONITORING OF RESPIRATORY VOLUME

Similar to flow measurement, the ideal measurement of volume should be an accurate accounting of the gas quantity moving into and out of the patient. However, delivered or exhaled V_T measurement is subjected to the same limitations of flow measurement because most anesthesia machines and ventilators determine volume by electrically or numerically integrating the corresponding flow signal.[222] Care must be taken to ensure any drifts or offsets from the flow transducer are minimized, given that their integration will result in errors in estimated volume. This may be accomplished by appropriately zeroing the transducer periodically, such as at the end of a breath. Although electronic or digital high-pass filters may be used to remove drifts and offsets in real-time, these tend to have long transient responses.[276b,c]

Finally, besides the pathophysiologic and monitoring applications described in this section, monitoring of pressures, volumes, and flows has been applied to monitoring, training, and education for neonatal resuscitation.[277]

Plethysmographic Monitoring

Respiratory inductance plethysmography (RIP) is a noninvasive respiratory monitoring technique that quantifies changes in the cross-sectional area of the chest wall and the abdominal compartments. The method is used to assess V_T, respiratory rate, adequacy of high-frequency oscillatory ventilation (HFOV), lung volume changes during tracheobronchial suctioning, and thoracoabdominal synchrony.[278] RIP relies on the principle that a current applied through a loop of wire generates a magnetic field normal to the orientation of the loop (Faraday's law) and that a change in the area enclosed by the loop creates an opposing current within the loop directly proportional to the change in the area (Lenz's law). Two elastic bands containing a conductor are used: one typically placed around the patient's chest, 3 cm above the xiphoid process; and the other around the abdomen. Each of these bands produces an independent signal representative of the thoracic and abdominal cross-sectional area, and the sum of these two signals calibrated against a known gas volume yields lung volume change.

There have been several pediatric applications of RIP to monitor V_T and respiratory rate, building on the advantage that a facemask, LMA, or ETT is not required for measurements.[279-281] The technique could also guide lung-protective ventilation strategies by facilitating the construction of PV curves for individual patients. These can be used to optimize lung recruitment, maintain an open lung, and limit overdistension (see the section on "Static Respiratory Mechanics"). RIP has found several applications in sleep studies.

Intraoperatively, RIP may be useful in areas for which accurate monitoring of V_T is required but not possible with the usual anesthesia machine monitors. This could occur with a shared airway (e.g., laryngotracheal surgery,[282] flexible and rigid bronchoscopy[283]), or a patient whose trachea is not intubated (e.g., monitored anesthesia care and noninvasive pressure support ventilation).

Limitations of intraoperative RIP include the fact that it cannot be used during thoracic and abdominal surgery, because of the need for the measurement bands. Also, the calibration characteristics of the device are affected by changes in the pattern of breathing.[284]

Respiratory Rate Monitoring: Apnea Monitoring

Apnea and bradypnea are life-threatening events frequently observed in the intraoperative and postoperative periods of anesthesia. Prematurity, morbid obesity, age, obstructive sleep apnea, and central nervous system depressant medications have been associated with risk of apnea or bradypnea.[285,286] Accordingly, many different approaches have been developed for detecting those events.[287,288] Two main types of apnea are observed: central and obstructive. Central apnea is defined as apnea resulting from a failure of the central nervous system to drive respiration. Obstructive apnea is that resulting from upper airway obstruction. Current monitors assess at least one of three processes occurring during breathing to detect apnea[288]: chest wall expansion, gas flow, and gas exchange.

Chest wall expansion is usually measured as follows:

1. Changes in thoracic electrical impedance (impedance pneumography) of the chest wall. The method is based on the changes in electrical conductivity of the chest to an electrical current as air moves in and out of the lungs during breathing and blood volume changes in the same period. This is because air is a poor electrical conductor and blood is a good electrical conductor. A low electrical current at high frequency is applied in two chest electrodes, corresponding changes in voltage of the chest are measured, and the impedance is continuously calculated from these. The technique is implemented in several commercial systems using routine electrocardiographic leads and is also used in home monitoring of neonatal apnea.
2. Inductive plethysmography (as described earlier).
3. Abdominal and chest fiberoptic and resistive strain gauges (a pressure pad placed alongside the infant's rib cage, pneumatic abdominal sensors) are used.
4. Electromyographic signal of respiratory muscles is not frequently used because of the low signal-to-noise ratio.

An important drawback of techniques based on chest expansion is their inaccuracy in the presence of movement. Thus obstructive apnea may be falsely assessed as normal respirations.[289]

Gas flow methods are based on measurements of different variables directly related to the presence of air flow in the airway:

1. Pressure gradients along the breathing circuit. This approach uses the Poiseuille principle ($\Delta P = k \times V$) and differential pressure transducers to detect flow.
2. Temperature of the breathed air in the nose or mouth is used.
3. Rapid response hygrometer is based on assessment of humidity in the exhaled air.

Techniques based on gas exchange focus essentially on exhaled CO_2, as routinely used in intubated patients in the operating room. In nonintubated patients, the use of specifically designed cannulae combining DO_2 and breathed gas sampling facilitates the monitoring of exhaled CO_2. Capnography allows for early detection of respiratory depression before O_2 desaturation, particularly when supplemental O_2 is administered.[290,290a] Off-line or in-line infrared sensors are the most common technique. Respiratory rate measurements using these techniques were more accurate than those obtained with thoracic impedance tomography in extubated patients in postanesthesia care units, even with supplemental O_2 at high flows.[291] Accurate end-tidal CO_2 measurements through a nasal cannula may be difficult in mouth breathers, including obese patients and those with obstructive sleep apnea. In such cases, a nasal cannula with an oral guide may improve measurement accuracy.[292] Simulation studies indicated that respiratory rate can be accurately monitored during esophagogastroduodenoscopies using a CO_2 sampling bite block or a nasal cannula with oral cup. The accuracy of $P_{ET}CO_2$ measurements depends on the device used, O_2 flow, the intensity of oral breathing, and minute ventilation.[293]

Pulse oximetry cannot be used as the primary monitor of apnea or bradypnea because O_2 desaturation occurs only late in a well-oxygenated apneic patient. However, pulse oximetry adds an additional level of safety combined with primary monitors of ventilation. For example, in a study using pulse oximetry and noninvasive capnography for continuous monitoring of 178 patients receiving patient-controlled analgesia, respiratory depression measured by O_2 desaturation occurred in 12% of the patients, in line with previous studies.[285] In contrast to previous estimates, episodes of bradypnea (respiratory rate < 10 breaths/min) were present in 41% of patients, far more frequently than the previously reported 1% to 2%.[294-296]

Respiratory rate monitoring is also critical to infant apnea monitoring. Combinations of transthoracic impedance and pulse oximetry may maximize the detection of true episodes of apnea in home monitors for neonatal apnea.[297] This is because pulse oximetry provides an additional level of monitoring in cases of poor performance of transthoracic impedance secondary to motion artifacts. The value of combining monitors of ventilation such as capnography with pulse oximetry to maximize the detection of alveolar hypoventilation has been confirmed.[298] Capnography allowed for early detection of arterial O_2 desaturation in cases of alveolar hypoventilation in the presence of supplemental O_2.

False-positive and false-negative alarms occur during apnea monitoring. The most dangerous conditions occur when artifacts are detected as breathing and alarms are not activated. Such artifacts include vibrations, cardiac motion, patient movement, and electromagnetic interference from other instrumentation. Impedance pneumographs are subject to cardiovascular artifacts, whereas pressure pads are subject to patient motion artifacts. A more common (yet less dangerous) problem is when an alarm sounds in a patient without apnea. Frequent causes include inadequate sensitivity settings, malfunctioning electrodes, and movement of the patient. Motion transducers based on sensing of acceleration were used in neonates undergoing HFOV, and results showed that monitoring of regional tidal displacement may enable the early recognition of deteriorating ventilation during HFOV that eventually leads to hypoxemia.[299] This study found that in approximately half of the cases, hypoxemia had causes other than slowly deteriorating ventilation.[299]

Current recommendations of the Anesthesia Patient Safety Foundation for Essential Monitoring Strategies to Detect Clinically Significant Drug-Induced Respiratory Depression in the Postoperative Period (http://www.apsf.org/initiatives.php), including opioid-induced ventilatory impairment, state that continuous electronic monitoring of oxygenation and ventilation should be available and considered for all patients, not only those at risk for postoperative respiratory insufficiency. This is because selective monitoring is likely to miss respiratory depression in patients without risk factors. These recommendations stress that maintaining status quo while awaiting newer technology is not acceptable, and that intermittent "spot checks" of oxygenation (pulse oximetry) and ventilation (nursing assessment) are not adequate for reliably recognizing clinically significant evolving drug-induced respiratory depression. Continuous electronic monitoring should not replace traditional intermittent nursing assessment and vigilance. All patients should have oxygenation continuously monitored by pulse oximetry. Capnography or other monitoring modalities that measure ventilation and airflow are indicated when supplemental O_2 is needed to maintain acceptable O_2 saturations. The recommendations also call attention to threshold-based alarm limits on individual physiologic variables, which may result in failure to recognize early signs of progressive hypoventilation by either being insufficiently, or too, sensitive (excess false alarms).

Unexpected death has been associated with three patterns of respiratory depression.[300-302] (1) Hyperventilation compensated respiratory distress (e.g., from sepsis, pulmonary embolus, or congestive heart failure): patients present initially with stable S_pO_2 and decreasing P_aCO_2 as metabolic acidosis develops with associated compensatory hyperventilation. High respiratory rate is typical of this pattern. Ultimately, a slow desaturation is followed by an abrupt fall in oxygenation as the ventilatory response to worsening acidosis fails. (2) Progressive unidirectional hypoventilation or CO_2 narcosis: frequently due to opioid or other sedative overdose, it is characterized by a rise in P_aCO_2 (and $P_{ET}CO_2$) initially because of decreased minute ventilation, often while S_pO_2 remains above 90%. (3) Sentinel rapid airflow/O_2 saturation reduction with precipitous S_pO_2 fall: observed in patients with obstructive sleep apnea, who are dependent on the arousal state to maintain oxygenation. Sleep results in precipitous hypoxemia during apnea with potential sudden arrest.

Imaging for Respiratory Monitoring

Imaging as a monitoring technique provides tremendous insight into pulmonary structure, function, and inflammation in both health and disease.[303-305] However, exposure to radiation and bulky devices has prevented its use at the bedside. Technologic advances have led to the introduction of new modalities with more compact equipment for clinical use. This may herald an important shift in respiratory monitoring toward the increased use of bedside imaging. Such improvements come with the advantages of less radiation exposure, noninvasiveness, and more detailed physiologic information.

CHEST RADIOGRAPHY

Chest radiography has been the traditional imaging method to assess intrathoracic conditions in the operating room, postoperative anesthesia care unit, and ICUs. Anesthesiologists should be familiar with basic radiologic findings representative of important pulmonary conditions such as interstitial infiltrates, hyperinflation, pneumothorax, pleural effusion, and consolidation. The image during chest radiography, as well as computed tomography, is based on the physical principle that x-rays reaching a detector (e.g., film) depend on tissue absorption, which varies linearly with tissue density. However, radiation exposure restricts frequency of use. Furthermore, technical difficulties limit image quality. These difficulties include reduced resolution caused by patient movement during acquisition, and image distortion related to proximity of the x-ray beam source to the film/detector and posterior position of the film cassette.

ULTRASONOGRAPHY

Lung ultrasonography is a technique increasingly used in the perioperative, critical care, and emergency settings in adults and children.[306-309] Critical and systematic approaches have proven that important clinical information can be obtained with lung ultrasonography at levels

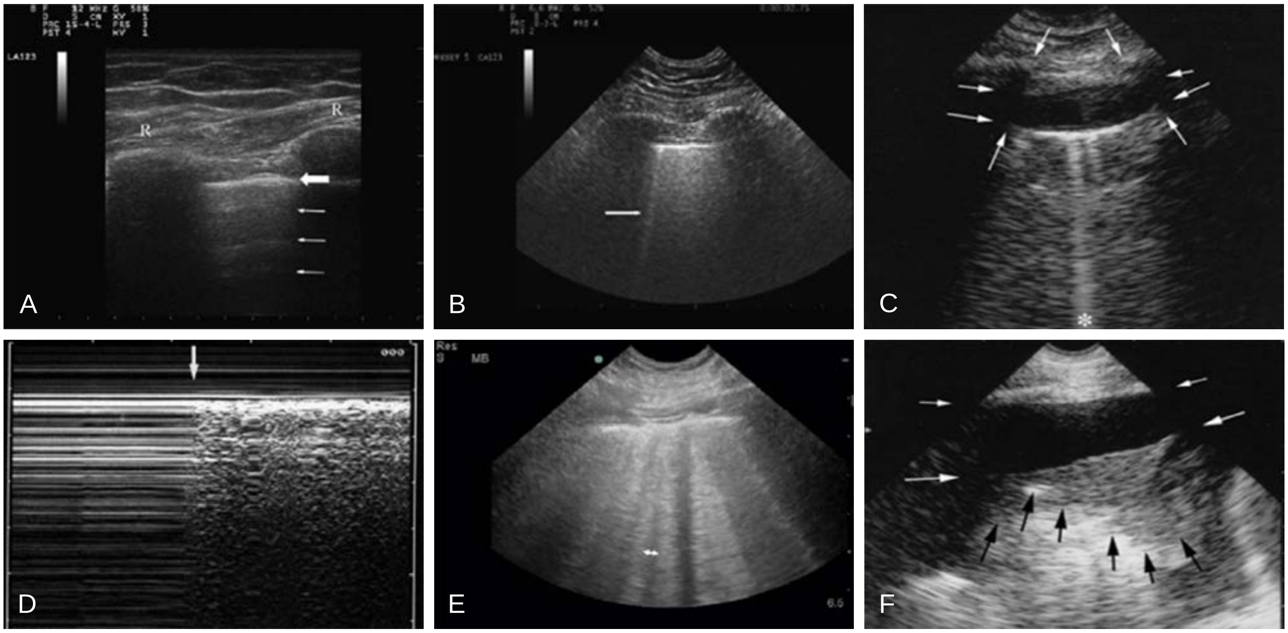

Fig. 41.27 (A) Typical thoracic view depicting adjacent ribs (R) producing acoustic shadowing. The white echogenic pleural line *(block arrow),* is approximately 0.5 cm below the ribs. A-line artifacts *(line arrows)* are seen at equidistant spaces below the pleural line; (B) B-line, or comet-tail artifact *(line arrow)*, is the hyperechoic artifact extending from the pleural line to the edge of the screen, erasing the A-line. A solitary B-line is a usual finding in normal lungs; (C) pleural effusion: image obtained at the posterolateral region showing the parietal pleural *(upper horizontal arrows)*, the rib shadows *(vertical arrows)*, and the visceral pleura (line indicated by the *lower horizontal arrows*) with the underlying lung. The dark anechoic region between the parietal and visceral pleura represents the pleural effusion. A B-line artifact *(asterisk)* originates from the lung and not from the pleural line, implying the presence of aeration; (D) M-mode of lung of lung ultrasound illustrative of the "lung point" for diagnosis of pneumothorax. The sudden inspiratory transition from a parallel line pattern indicative of absence of lung motion (pneumothorax) to a granular pattern indicative of lung tissue can be observed *(arrow)*; (E) Interstitial syndrome case showing B-lines 7 mm or less apart. Notice the increased number of B-lines as compared to panel (B). The pleural line *(arrow)* and ribs are also appreciated; (F) Lung consolidation with pleural effusion. As in (C), the image was obtained at the posterolateral region showing the parietal pleura *(upper horizontal arrows)* and the visceral pleura and lung *(lower horizontal arrows)* with an anechoic pleural effusion between them. Lung tissue denser than that presented in (C) with gas barriers *(vertical arrows)*. This indicates pleural fluid with alveolar fluid often seen in critically ill patients. ([A, B, D, E] From Turner JP, Dankoff J. Thoracic ultrasound. *Emerg Med Clin North Am*. 2012;30:451–473, ix. [C, F] From Lichtenstein DA. BLUE-protocol and FALLS-protocol: two applications of lung ultrasound in the critically ill. *Chest*. 2015;147[6]:1659–1670. doi: 10.1378/chest.14-1313.)

comparable to computed tomography.[309] Such features add to the advantages of practicality, low cost, and absence of radiation or other significant biologic side effects. Excellent reviews have been published, and the reader should refer to those for additional learning.[308,309]

Lung ultrasonography has been applied successfully in the assessment of pneumothorax, interstitial syndrome (i.e., cardiogenic and permeability pulmonary edema), lung consolidation, and pleural effusion. Currently available multipurpose ultrasonography probes can be used for specific portions of the pulmonary exam according to their characteristics. For instance, the high-frequency (10-12 MHz) linear array probe allows for detailed examination of the pleura and superficial changes, such as pneumothorax. This probe's limitations include its size, which impedes access to larger areas of lung tissue because of the interference of the ribs, and high frequency, which limits assessment of deeper structures. A lower frequency (1-5 MHz) probe provides improved depth penetration and is used to assess supradiaphragmatic structures (pleural space, lung). To optimize lung visualization with a single probe, frequently probes with emission frequencies of 5 to 7 MHz are used and are usually small with a tip shaped so that an acoustic window on the lung parenchyma can be obtained on intercostal spaces. The 5 MHz microconvex probe is frequently favored,[306,307] although curvilinear and phased-array probes are also appropriate.[308]

When examining the patient, a methodical approach should be used to ensure comprehensive assessment of lung structure and function. The I-AIM (Indication, Acquisition, Interpretation, Medical Decision-Making) framework has been recently proposed for point of care lung ultrasound.[308] A complete exam involves the bilateral assessment of the anterior, lateral, and posterior lung. Although protocols vary, in the supine patient, each hemithorax should be assessed in at least six zones during emergencies: two anterior (separated by the third intercostal space), two lateral, and two posterior. In routine assessments, 8-zone and 12-zone protocols are most commonly used.[308,310,311] Because of the significant acoustic impedance differences between air, tissue, and bone (ribs), thoracic ultrasound is based primarily on characteristic artifacts and not only on the visualization of anatomic structures.[312] Videos of 1 to 2 breaths should be acquired to take advantage of the lung dynamics in the findings. Machine settings should be optimized at the start of the examination.[308] Usually, studies are initiated with the identification of the ribs as hyperechoic lines producing significant ultrasonography shadow (Fig. 41.27*A*), followed by visualization of the pleural line approximately 0.5 to 1.0 cm deeper and between the ribs. This is typically a bright, slightly curved line. These are major structures to be identified, because many pathologies of relevance to the anesthesiologist affect their observed pattern. In the normal lung, lung sliding represents the

movement of the visceral on the parietal pleura during respiration and is another key sonographic finding to be appreciated. The magnitude of the movement is larger in regions closer to the diaphragm than those near the lung apex.

Below the pleura, hyperechoic horizontal reverberation artifacts at regular distances are referred to as A lines (see Fig. 41.27*A*). Another artifact is the B line, a discrete laser-like vertical hyperechoic reverberation artifact that arises from the pleural line (previously described as "comet tails"), extends to the bottom of the screen without fading, moves synchronously with lung sliding, and erases A lines (see Fig. 41.27*B* and *C*). Solitary B lines are a normal finding in the normal lung, and increased numbers are observed in disease. Based on the recognition of such artifacts, pathologic conditions are identified.[306-308,313] Most acute disorders involve the lung surface, and this explains the utility of thoracic ultrasound in visualizing them. Ultrasonography findings for pneumothorax are the absence of lung sliding, B lines, and lung pulse, and the presence of lung points.

Pleural effusions are characterized by a usually anechoic space between the parietal and visceral pleurae (see Fig. 41.27*C* and *F*) and by respiratory movement of the lung within the effusion ("sinusoid sign"). The presence of echogenic material within the effusion suggests an exudate or hemorrhage, although some exudates are anechoic. Most transudates are anechoic. The M-mode ultrasound scan shows parallel lines indicative of no moving structure underlying the probe. The ultrasonographic finding designated as a lung point is found in the presence of pneumothorax and represents the imaging of the cyclic transition during breathing from the absence of any sliding or moving B lines at a physical location (i.e., air with no lung parenchyma) to the visualization of lung sliding, B lines, or altered A lines indicative of lung tissue (see Fig. 41.27*D*).[307,314] Bedside ultrasound scans can detect pneumothorax with sensitivity similar to a CT scan.[306,307]

An interstitial syndrome is characterized by the presence of multiple B lines. A positive region is defined by three or more B lines in a longitudinal plane between two ribs (see Fig. 41.27*E*).[307] Lung consolidation is characterized sonographically by a subpleural echo-poor region or one with tissue-like echo-texture (see Fig. 41.27*F*). Lung consolidations may be caused by infection, pulmonary embolism, lung cancer and metastasis, compression atelectasis, obstructive atelectasis, and lung contusion. Additional sonographic signs that may help determine the cause of lung consolidation include the quality of the deep margins of the consolidation, the presence of comet-tail reverberation artifacts at the far-field margin, the presence of air or fluid bronchograms, and the vascular pattern within the consolidation. Advances in clinical research and experience in lung ultrasonography allowed for the proposal of an algorithm to assess severe dyspnea in the acute setting (Fig. 41.28). The denominated BLUE protocol is a stepwise ultrasonographic approach to the patient with acute respiratory failure that aims at expeditious diagnosis with 90.5% accuracy.[309,313,315]

ELECTRICAL IMPEDANCE TOMOGRAPHY

Electrical impedance tomography (EIT) is a noninvasive and radiation-free imaging modality used to assess regional lung function at the bedside. The method is clinically available and has moderate to low spatial resolution but high temporal resolution, thus allowing for assessment of regional ventilation in real-time.[235a,305,316] Its use in estimating regional lung volume and optimizing mechanical ventilation settings brought significant attention to applications in ICUs and operating rooms.[305]

EIT is based on electrical impedance, a physical variable that reflects the opposition to the passage of a current through an object when a voltage is applied across it.[317] The impedance of biological tissues depends on the tissue composition. High concentrations of electrolytes, extracellular water content, large cells, and number of cell connections by gap junctions as present in blood and muscles reduce impedance. Air, fat, and bone have high electrical impedance. Pathologic changes of tissue composition influence impedance. These include extravascular lung water (EVLW) (e.g., pulmonary edema), intrathoracic blood volume, fluid in cavities (pleural effusion, pericardial effusion, bronchial and alveolar fluid), foreign bodies (pleural drain), and lung fibrosis (e.g., after ARDs or as a primary disorder). During the breathing cycle, thoracic bioimpedance is influenced fundamentally by both ventilation and perfusion.

EIT relies on an array of electrodes (typically 16-32) around the chest region of interest. The location is chosen based on the clinical information desired, usually at the fifth intercostal space for standard lung assessment. The impedance information is provided in the form of a functional EIT image, or EIT waveforms that quantify changes in lung volume or perfusion in the studied thoracic cross section. Usually, images are presented with pixels representing relative impedance change, so-called functional EIT, because air corresponds to high impedances and fluid and tissue to low impedances, and the image represents regional lung ventilation. Absolute EIT (a-EIT) is the modality in which the image represents the actual impedance values. Direct assessment of lung conditions can be accomplished by comparing low impedance (e.g., hemothorax, pleural effusion, atelectasis and lung edema) with high impedance (e.g., pneumothorax, emphysema).[318] EIT has compared successfully with standard methods, including computed tomography.[319]

Because the technique provides direct real-time assessment of changes in regional aeration, several applications related to regional lung function have been identified.[316,319] These include the effect of induction and tracheal intubation on the expiratory lung level and regional ventilation in children (Fig. 41.29)[320]; perioperative monitoring of the distribution of ventilation during spontaneous and controlled breathing,[321,322] including HFOV[235a,278,323]; effects of PEEP on regional ventilation during laparoscopic surgery[324]; the magnitude of bedside lung recruitment; and PEEP titration with assessment of alveolar collapse and hyperdistention in ARDS[325] and obese patients.[326] EIT may also allow for real-time detection of pneumothorax.[327] Recent advances show the potential of EIT to provide measurements of regional perfusion,[319,328] which could be valuable for bedside assessment of $\dot{V}/\dot{Q}$ matching during spontaneous and mechanical ventilation.

Point of Care Tests

Point-of-care testing (POCT) is the performance of laboratory measurements near the site of patient care. POCT technology includes portable analyzers and use of small blood samples. For the anesthesiologist, it implies the availability of rapid, precise, and accurate measurements in operating rooms and ICUs. POCT yields improvements in patient outcome through expeditious detection of physiologic deterioration and prompt treatment. Respiratory monitoring is a major element of POCT and includes analysis of arterial blood gases (P_aO_2, P_aCO_2, pH), Hb, and lactate.

Blood gas measurements can be obtained with acceptable levels of accuracy and precision with POCT.[329-331] For instance, different platforms for arterial blood gases and Hb were found to show coefficients of variation of

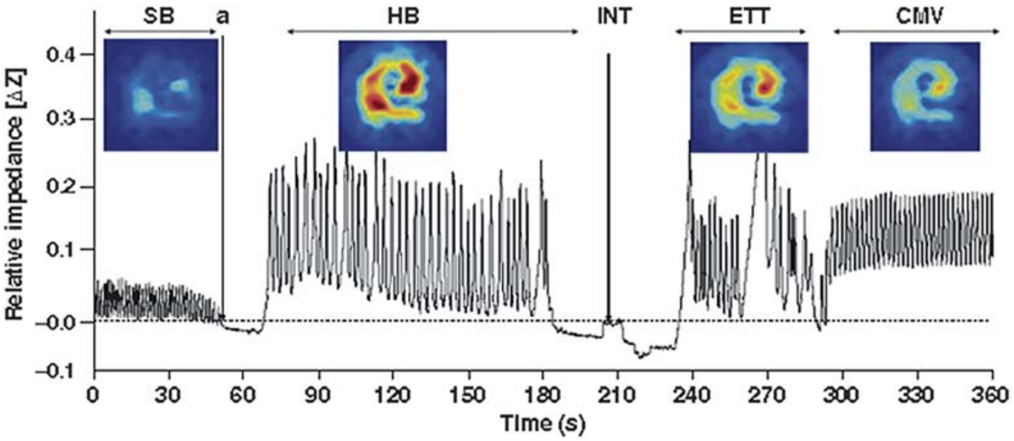

Fig. 41.29 Relative impedance signal at five key stages during induction of anesthesia in children. (a) There is a small impedance signal during spontaneous breathing *(SB)* as muscle paralysis develops. Effective hand bagging *(HB)* produces a high intensity signal, which is zeroed during tracheal intubation *(INT)*. Distribution of regional impedances during hand bagging with the endotracheal tube *(ETT)* and conventional mechanical ventilation *(CMV)* are also visualized. (From Humphreys S, Pham TM, Stocker C, Schibler A. The effect of induction of anesthesia and intubation on end-expiratory lung level and regional ventilation distribution in cardiac children. *Paediatr Anaesth*. 2011;21:887–893.)

approximately 3% to 6%.[330,331] Accuracy is present in wide ranges of P_aO_2 and pH[329-331], and shows bias of some devices for P_aCO_2.[331]

Hb is measured using either conductivity-based methods where hematocrit is assessed and the Hb concentration calculated (Hb [g/dL] = hematocrit × 0.34) or with optical methods, such as using the azide-metHb reaction and photometry absorbance.[332] Conductivity-based Hb measurements can be less than those reported by standard systems, with a clinically significant bias of at least −1.2 g/dL in the Hb range of 8.5 to 14.2 g/dL and a trend to underestimate the Hb value at low ranges.[330,331] Variable measurement agreement across devices, and bias resulting from inspired O_2 fraction are issues that still limit noninvasive Hb assessment.[331,333,334]

The site of blood sampling can influence POCT results. For capillary blood samples obtained from finger and ear punctures, a significant correlation exists between optical-based and automated laboratory Hb analysis, with a nonsignificant bias. Fingerstick samples may approximate standard laboratory Hb measurements better than earlobe samples.[22] Capillary blood samples (lancet puncture to middle or ring finger and fourth drop used) in patients with gastrointestinal bleeding resulted in high deviations (>1 g/dL) in 21% of cases and very high deviations (>2 g/dL) in 4% of cases.[335] In critically ill patients, poor agreement with reference measurements is reported,[336] especially with capillary blood samples and in patients with extremity pitting edema. POCT proved relevant in the assessment of arterial blood gases during pseudohypoxemia (also called "spurious hypoxemia" and "leukocyte larceny"). This is a known cause of inaccurate blood gas measurements and occurs when P_aO_2 is reduced by increased O_2 consumption as a result of markedly elevated white blood cell counts in the arterial blood sample. Measurement error is further aggravated by delayed laboratory analysis or incorrect sampling. Pseudohypoxemia occurs not only in hyperleukocytosis but also in thrombocytosis associated with polycythemia vera.

As POCT progresses, relevant limitations will need to be addressed, including cost, accuracy, data management, and evidence for improved outcomes. Contrary to some expectations, availability of POCT in academic centers does not increase the number of tests performed.[337] Characteristics of individual institutions should be considered before POCT is implemented. For instance, POCT blood-gas analysis may offer minimal time savings and cost benefits compared with central laboratory analysis in an institution with short turnaround time.

Respiratory Monitoring in Special Conditions

As methods for life support are advanced, the physiologic patterns that serve as the basis for assessment of gas exchange and respiratory mechanics can be dramatically changed. This occurs, for instance, during HFV when significant reductions in V_T are combined with large increases in respiratory rate. During rigid bronchoscopy or laryngeal interventions, the anesthesiologist is required to share management of the airway with the surgeon. This may result in intermittent loss of information regarding airway flow, volume, and pressure, as well as end-tidal gas concentration. In these situations, clinical assessment based on physical examination (i.e., inspection, auscultation) becomes paramount. Specific considerations for respiratory monitoring in special conditions are detailed in the next section.

HIGH-FREQUENCY VENTILATION

HFV is a ventilatory mode using V_T smaller than the anatomic dead space, 10-fold to 50-fold higher respiratory frequencies, and high instantaneous flow rates. The HFV is a broad term encompassing various modalities. These include high-frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV), both of which allow for passive exhalation, as well as HFOV, in which exhalation is actively driven by the device. The mechanisms for gas exchange during HFV are complex and include convective transport, turbulence, pendelluft, velocity profile distortion and asymmetry, Taylor dispersion, molecular diffusion, collateral ventilation, and cardiogenic mixing.[338-340] This method results in a fundamentally different relationship for CO_2 elimination ($\dot{V}_{CO_2}$) compared with conventional ventilation.[341] For example, during conventional ventilation,

$$\dot{V}_{CO_2} \propto f\,(V_T - V_D) \tag{41.39}$$

where f is the breathing frequency and V_D is dead space volume. However, during HFOV[342,342a],

$$\dot{V}_{CO_2} \propto f\frac{V_T^2}{V_D} \tag{41.40}$$

The use of HFOV for neonates in respiratory distress failing conventional ventilation is common.[343-345] However, its use in adult patients with ARDS has been limited in light of recent clinical trials,[345a,b] despite the sound physiologic rationale of using high mean airway pressures and low V_T to achieve alveolar recruitment without overdistention.[346-350]

Most high-frequency oscillators use pistons to actively drive flow into and out of the airway at respiratory rates between 3 to 20 Hz.[351,352] However, some oscillators, and most jet ventilators, rely on solenoid valves.[353-355] With HFOV, fresh gas and CO_2 may be removed by a continuous bias flow of warmed, humidified gas past the proximal end of the ETT, and mean airway pressure is regulated by an adjustable valve venting the bias flow and exhaled gas from the circuit. These devices may be either pressure or time cycled, and both the mean airway pressure and oscillatory pressure amplitude are displayed on the console to the clinician. However, for the frequencies used during HFV, a significant portion of the oscillatory pressure amplitude results from the inertia of the gas column contained in the breathing circuit and the patient's airways, and thus it should not be used as a surrogate for lung distention.

Clinically useful physiologic information inferred from airway flow and pressure measurements is somewhat limited during HFV. During conventional mechanical ventilation, airway pressure and flow are related according to basic mechanical properties of the respiratory system, such as airway resistance and tissue compliance. However, during HFV, airway pressure and flow reflect complex resistive and inertial gas properties in the central airways. Many investigators have assessed respiratory mechanics during HFV by transiently switching patients to conventional mechanical ventilation to obtain basic estimates of resistance and compliance,[356] or even making intermittent low-frequency oscillatory measurements to measure airway and tissue properties.[357] The pressure transmission index, defined as the ratio of the pressure measured directly in the trachea to the pressure at the proximal end of the breathing circuit (i.e., the pressure amplitude measured at the oscillator), is strongly correlated with tissue elastance.[357,358]

An important component of monitoring during any form of HFV is the assessment of mechanical function. Many important physiologic parameters, such as mean airway pressure and V_T, are not explicitly controlled by most high-frequency ventilators.[358a,b] Thus the relationship between pressure transduced at the proximal end of the breathing circuit and the V_T delivered to the patient is difficult to assess. Indeed, this relationship is highly nonlinear,[343] and it depends on frequency, gas composition and inertia, and the overall mechanics of the patient's respiratory system.[235,276] Given the important role that V_T plays in CO_2 elimination during HFV (Eq. [41.40]), accurate measurement of airway flow is important for the development and standardization of clinical trials.[359] Hot wire anemometry yields the most accurate estimates of airway flow and delivered V_T during HFOV compared with other measuring devices.[235,276]

Adequacy of gas exchange is essential during HFV. Analysis of arterial blood gas measurements should be performed within 30 minutes of any change in ventilator settings, and at least twice per day on stable settings.[346] Whereas oxygenation is usually assessed with continuous pulse oximetry, CO_2 elimination is more technically challenging to monitor. Attempts have been made to incorporate various forms of capnography into HFV circuits,[360-363] with varying degrees of success. Depending on where exhaled gases are sampled, there may be adequate correlation between $P_{ET}CO_2$ and P_aCO_2 during HFV.[362,363] This is often a reflection of the slower response time of many sidestream CO_2 analyzers.[171]. The PCO_2 sampled at the airway opening may thus underestimate the true alveolar CO_2 levels.[361] The most accurate measurement of alveolar PCO_2 is obtained when it is measured at the very distal tip of the ETT,[364] although this is not always clinically feasible. Transcutaneous measurements of PCO_2 may hold considerable promise for assessment of CO_2 clearance during HFV.[365]

Although HFOV has not been shown to improve outcomes in adult patients with ARDS,[345a,b] this finding may reflect the variable effects of frequency, amplitude, and mean airway pressure with oscillating of a heterogeneously injured lung,[342a,348] as well as the poorly understood phenomena of gas distribution, volume recruitment, and $\dot{V}/\dot{Q}$ matching in individual patients. Recent studies suggest that oscillation using multiple simultaneous frequencies may improve the efficiency of gas exchange, reduce the heterogeneity of parenchymal strain, and maintain lung recruitment at lower mean airway pressures.[235a,365a] Despite significant gaps in our understanding of the use of HFOV in acute respiratory failure, this modality may still have some clinical application as part of a lung-protective ventilatory strategy, particularly in patients with severe hypoxemia.[290a] Future clinical trials will guide both therapy and technologic development of HFOV,[347] thus providing a scientific basis for the rational use of this technology in critically ill patients.

JET VENTILATION

Jet ventilation is commonly used for procedures in which the surgeon requires unobstructed access to the airway.[366] During inspiration, O_2 or an O_2-air mixture is applied under high pressure to the airway through either a specialized catheter or a rigid bronchoscope. This jet of gas, along with entrained air from the surrounding environment, leads to insufflation of the lungs. Expiration takes place through passive recoil. The entire system is open to the environment, thus leading to significant escape of respiratory gases.[354]

Oxygenation during jet ventilation can be adequately monitored using pulse oximetry. Ascertaining the presence and adequacy of ventilation, especially during HFJV, is more challenging because the composition and volume of the exhaled gases cannot be directly measured. Arterial sampling of P_aCO_2 is accurate but intermittent and invasive. Gas can be sampled at the distal end of the catheter or rigid bronchoscope through a dedicated channel. Quantitative capnography during HFJV does not accurately reflect P_aCO_2 because V_T is smaller than dead space.[367] This problem can be overcome by the intermittent suspension of HFJV or reduction in frequency to 10 breaths/min or less. $P_{ET}CO_2$ measurements obtained in this manner accurately reflect the P_aCO_2 and allow the intermittent monitoring of ventilation.[363,368-370] The measurement of transcutaneous PCO_2 ($P_{tc}CO_2$) is noninvasive and continuous. Although $P_{tc}CO_2$ is not as accurate as capnometry and has a slower response time to changes in P_aCO_2, its use may allow for tracking of changes in P_aCO_2.[370] The absence of V_T and continuous $P_{ET}CO_2$ monitoring precludes standard ventilator disconnect monitoring during intraoperative HFJV. RIP, which uses changes in the inductance of bands placed around the chest to monitor respirations, has been demonstrated to discriminate reliably between the presence and absence of HFJV and may be developed as a monitor to detect disconnect or the absence of adequate thoracic excursion during HFJV.[282]

PATIENT TRANSPORT

Intrahospital transport of critically ill patients is a frequent occurrence. Transport of adult and pediatric patients from locations with advanced monitoring to more remote locations is fraught with difficulty, ranging from simple equipment malfunction to major disasters.[371-373] Complex monitoring and numerous pieces of equipment are often required for safe transfer, especially when additional devices such as extracorporeal membrane oxygenators and ventricular assist devices are present. The lack of standardized monitoring techniques and terminology explains the widely reported discrepancies in the incidence of adverse events. Overall, a high incidence of respiratory complications following transport has been reported.[372-374]

Respiratory monitoring during transport should ideally be the same as that in the operating room or ICU before relocation. In practice, at least clinical signs (e.g., skin color, chest expansion, auscultation, endotracheal secretions), pulse oximetry, and respiratory rate, together with EKGp and blood pressure, should be monitored throughout intrahospital transport. If a transport ventilator is used, airway pressures should be readily available in numeric or graphic formats. Human factors are essential during transport, and a specialized transport team using standardized management procedures with preparatory, transfer, and post-transport stabilization phases likely limits the frequency of adverse events.[375-377] This is particularly important when high-risk patients are involved.[376] Equipment and medications needed to establish and maintain a secure airway and hemodynamics should be available during any transfer. Adequate O_2 supply with functioning low-pressure alarms should be verified during pretransport preparation. A transport ventilator can provide better oxygenation and reduce variability in pH and PCO_2 compared with manual ventilation.[374,378] The transfer phase may require several professionals under the coordination and supervision of an attending anesthesiologist.

Automated Data Systems

Electronic anesthesia records are part of routine clinical practice in many institutions. Such systems provide data from medical devices, clinical information management systems, and laboratory data. The availability of large amounts of real-time data in digital form allows for introduction of new approaches to monitoring that may have been conceptualized, but not yet clinically implemented. In fact, although decision-support research has been done for years, little progress has been made in clinical decision support for the acute management of unstable patients, a major challenge in the operating room and ICU.[379-381] Computerized monitoring has significant potential to improve clinical monitoring.[379,382] However, it has limitations resulting from typical requirements not well-suited for human performance, such as monitoring graphic displays over extended periods, or the execution of overt responses to low-probability events. Humans are limited in their ability to analyze large quantities of data accurately and continuously. Accordingly, computer algorithms that identify subtle but meaningful trends in physiologic data are desirable. Such tools require relevant contextualization of measurement to improve accuracy, as well as minimization of false-negative and false-positive alarms. This automated monitoring should depend not only on timely measurements, but also on prior information. Alarms should not be fixed to specified thresholds, but rather dynamically adapted to information as it becomes available. Algorithms with established clinical rules provide the opportunity to detect subtle changes in time-series data,[383] which exceed human discrimination.[384] Such automated systems minimize monitoring failures and promote timely responses, thus enhancing the performance of anesthesia delivery during long periods. Some tools of respiratory monitoring have been assessed in adult and pediatric populations.[379,385-387] Data banks have been developed for research.[381] Another potential interest in these systems is that of creating closed-loop systems, such as those currently implemented to adjust settings in commercial mechanical ventilators.[386,388]

Although these methods are not currently established for clinical use, they are expected to find increasing application as reliable monitoring algorithms are implemented and validated. Such automated systems allow for the implementation of additional levels of safety. The detection of potentially dangerous events, such as continuously low S_aO_2 or the absence of $P_{ET}CO_2$ measurements for several breaths, can generate an automated alarm, a screen alert, or an automated page to the supervising anesthesiologist.[389] In a different condition, for example when changes in oxygenation occur over a period of minutes, improved processes should be directed to the anesthesia provider in direct contact with the patient, to initiate prompt treatment, assess artifacts, and/or call for assistance.[389]

Additional Monitored Variables

NITROGEN WASHOUT AND END-EXPIRATORY LUNG VOLUME

There has been a resurgence of interest in the use of nitrogen washout methods for adult[390,391] and pediatric[392] patients. Nitrogen washout techniques are found in commercial mechanical ventilators for intensive care use. The main parameter of interest has been the end-expiratory lung volume, a potentially valuable measurement to optimize lung expansion during mechanical ventilation, and for the assessment of ventilatory interventions such as PEEP adjustment.[391] The measurements are performed by introducing a step change in the inspired air (traditionally from room air to 100% O_2, in current systems a nitrogen washout/wash-in method with 10% to 20% change in F_IO_2) and solving mass balance equations for the lung volume. In patients with ARDS, measurements of end-expiratory lung volume demonstrated good accuracy and reproducibility, with a coefficient of variation of less than 4%.[391] In 30 intensive care patients undergoing computed tomography for clinical reasons, the end-expiratory lung volume measured with the modified nitrogen washout/wash-in technique was well correlated ($r^2 = 0.89$) with computed tomography measurements with a bias of 94 ± 143 mL (15 ± 18%, $P = .001$), within the limits of accuracy provided by the manufacturer.[390] Nitrogen washouts can also provide measures of ventilation heterogeneity.[392]

TRANSCUTANEOUS MEASUREMENTS OF PARTIAL PRESSURES OF OXYGEN AND CARBON DIOXIDE

Gas exchange is a dynamic and at times rapidly changing process. Conventional direct measurements of arterial blood gases, although still the gold standard for P_aO_2, P_aCO_2, and pH monitoring, provide only an isolated picture of that process. Expeditious assessment of circulating blood gases could facilitate faster initiation of required therapy and adjustment of implemented ventilation. A method for noninvasive continuous monitoring of P_aO_2 and P_aCO_2 is a current clinical need.

Transcutaneous measurements of PCO_2 ($P_{tc}CO_2$), in addition to transcutaneous PO_2 ($P_{tc}O_2$), aim to provide noninvasive estimates of arterial CO_2 and O_2, or at least trends associated with them. These measurements have been useful in intensive care management of neonates and infants,[393] and in the fields of wound healing and hyperbaric O_2 therapy. An advantage is that transcutaneous monitoring can be applied when expired gas sampling is limited such as during HFOV, apnea testing, and noninvasive ventilation. The measurements are based on the diffusion of O_2 and CO_2 through the skin. Because the skin is not entirely permeable to gases, warming is used to facilitate gas diffusion. Such an increase in temperature (usually 42°C-45°C) promotes increased O_2 and CO_2 partial pressure at the skin surface resulting from changes in structure of the stratum corneum that increase diffusion and dermal hyperemia and shift the Hb dissociation curve. This process ultimately results in arterialization of the regional blood. $P_{tc}O_2$ and $P_{tc}CO_2$ are influenced not only by the arterial gas partial pressures but also by skin O_2 consumption, CO_2 production, and regional blood flow. Accordingly, $P_{tc}O_2$ is usually lower than P_aO_2, and $P_{tc}CO_2$ is usually higher than P_aCO_2.

O_2 transducers are electrochemical polarographic Clark-type electrodes in which the rate of chemical reaction is related to an electrical signal proportional to the O_2 concentration. For CO_2, a transducer using a pH electrode to measure PCO_2 (Stow-Severinghaus electrode) is used, where a change in pH is proportional to the logarithm of the PCO_2 change. For CO_2 monitors, a temperature correction factor is used to estimate P_aCO_2 from $P_{tc}CO_2$. In vivo correction is available in some devices based on arterial blood gases. The thin epidermal layer of infants facilitates the measurements, in contrast to the diffusion barrier introduced by the thicker adult skin. A lower electrode temperature in $P_{tc}CO_2$ monitoring produces systematic bias of the transcutaneous electrode. However, in very preterm babies, monitoring at 40°C or 41°C to reduce the risk of burns is possible, provided a bias correction of 12% to 15% is applied.[394]

The main application of $P_{tc}CO_2$ is in the neonatal ICU population.[393] Even in very low-birth-weight infants, the mean difference between $P_{tc}CO_2$ and P_aCO_2 is 3.0 mm Hg (95% confidence interval, 0.2 to 6.0 mm Hg; $P < .05$).[395] In addition, $P_{tc}CO_2$ may be used to assess the efficacy of mechanical ventilation continuously during respiratory failure. In this setting, in children 1 to 16 years, $P_{tc}CO_2$ was more accurate and precise than $P_{ET}CO_2$ in relation to P_aCO_2. $P_{tc}CO_2$-P_aCO_2 differences were 2.3 ± 1.3 mm Hg in children 1 to 3.4 years old and 2.6 ± 2.0 mm Hg in children 4 to 16 years old.[393] $P_{ET}CO_2-P_aCO_2$ differences were larger (6.8 ± 5.1 and 6.4 ± 6.3 mm Hg) for the same age ranges. When compared with $P_{ET}CO_2$, $P_{tc}CO_2$ monitoring is equally accurate in patients with normal respiratory function. Accuracy and precision in the perioperative period of cardiac surgery for congenital heart disease in infants and children were better for $P_{tc}CO_2$ than $P_{ET}CO_2$ in relation to P_aCO_2, with the exception of patients receiving significant amounts of vasoactive medications and in low cardiac output states.

In adults, $P_{tc}CO_2$ has proven to be a less accurate and precise surrogate for P_aCO_2. Nonetheless, $P_{tc}CO_2$ could be suitable for specific conditions. Laparoscopic surgery with prolonged pneumoperitoneum is one condition in which $P_{tc}CO_2$ may be a more accurate estimate of P_aCO_2 compared with $P_{ET}CO_2$,[396] even for trending P_aCO_2.[397] During deep sedation for ambulatory hysteroscopy in healthy patients, earlobe $P_{tc}CO_2$ agreed better with P_aCO_2 than did nasal sidestream $P_{ET}CO_2$, with lower bias (1.7 vs. –7.0 mm Hg) and smaller mean differences to $PaCO_2$ (3.2 ± 2.6 vs. 8.0 ± 6.0 mm Hg).[398] The sensitivity of the $P_{tc}CO_2$ monitor for detecting P_aCO_2 values higher than 50 mm Hg was also greater than for $P_{ET}CO_2$ (66.7% vs. 33.3%; $P < .01$).[398] $P_{tc}CO_2$ is also helpful during weaning from mechanical ventilation after off-pump coronary artery bypass graft.[399] In adults admitted to an emergency department for acute respiratory failure, agreement between P_aCO_2 and $P_{tc}CO_2$ was 0.1 mm Hg, and the limits of agreement were from −6.0 to 6.2 mm Hg). In patients undergoing noninvasive ventilation, unacceptably wide variability may be observed.[400] In mechanically ventilated ICU patients, $P_{tc}CO_2$ correlated better and with less bias to P_aCO_2 than $P_{ET}CO_2$ even if still with sizeable variability (mean $P_{tc}CO_2 - P_aCO_2 = 2.2 \pm 5.7$ mm Hg).[401] $P_{tc}CO_2$ does not replace $P_{ET}CO_2$ monitoring, which remains the standard of care to confirm intratracheal placement of the ETT following intubation, or to actuate a disconnect alarm in the operating room.

$P_{tc}O_2$ from normal to extremely low-birth-weight infants agreed well with P_aO_2 measurements, with mean $P_{tc}O_2-P_aO_2$ difference 2.3 (−1.5 to 6.8) mm Hg, clinically acceptable in current neonational ICUs. $P_{tc}O_2$ in neonates is additionally important to detect hyperoxia, which is not feasible with pulse oximetry. The use of $P_{tc}O_2$ in adults has been focused on wound management, peripheral vascular disease, and hyperbaric medicine. Although attempts for applications in adults were promising, such as the use of $P_{tc}O_2$ to support resuscitative efforts,[402] measurements following off-pump coronary artery surgical procedures still present very high variability.[403] The dependence of $P_{tc}O_2$ on low-flow states has been used in conjunction with analysis of arterial blood gases to estimate adequacy of cutaneous blood flow and, by inference hemodynamic, stability.[404,405]

In summary, transcutaneous measurements are favorably positioned for continuous gas exchange monitoring in neonates and infants. In contrast, widespread applications of transcutaneous techniques in the perioperative settings are still hindered by limitations, such as poor cutaneous blood flow, need for frequent calibration, slow response time, and risk for skin burns with prolonged application.

LUNG WATER

Pulmonary edema is a hallmark of lung injury. It can result from increased hydrostatic pressure in the pulmonary capillaries (cardiogenic), increased permeability of the alveolar capillary membrane (noncardiogenic), and reduced lymphatic drainage from the lungs. Such mechanisms can be caused by pulmonary or extrapulmonary factors. For these reasons, interest in the development of methods to quantify EVLW has been considered, because this may assist in the diagnosis and management of those conditions, including early detection, differential diagnosis, fluid therapy, diuretics, and mechanical ventilation.[406] In patients, assessment of pulmonary edema is made with imaging techniques (e.g., chest radiography, ultrasonography, and computed tomography), thermodilution, bioimpedance, bioreactance, and remote dielectric sensing.

Imaging Techniques

The method used primarily in clinical practice remains bedside chest radiograph. It allows for semiquantitative assessment of EVLW, its distribution, and its possible etiology. The chest radiograph has limited diagnostic accuracy. This is because (1) edema may not be visible until the amount of lung water increases by 30%[407]; (2) any radiolucent material that fills the air spaces (e.g., alveolar hemorrhage, pus, and bronchoalveolar carcinoma) will produce a radiographic image similar to that of pulmonary edema; (3) technical issues including rotation, inspiration, positive-pressure ventilation, patient position, and underpenetration or overpenetration can reduce sensitivity and specificity; and (4) substantial interobserver variability exists in interpretation of chest radiographs.[408,409] Computed tomography is another radiographic technique to quantify EVLW. In animal experiments, computed tomography densitometry could detect an increase in EVLW by as little as 50%.[162] Computed tomography-based studies indicated that significant hypoxemia secondary to pulmonary edema may not develop until the increase in EVLW approaches 200% to 300%.[163] Lack of portability and high radiation exposure limit the use of computed tomography as a continuous intraoperative monitor. Positron emission tomography[165] and nuclear magnetic resonance[166] are imaging techniques that can assess lung water. However, they are not amenable for routine clinical use in the perioperative setting. Lung ultrasonography is garnering greater acceptance as another method for assessing lung edema.

Indicator Dilution Methods

Such measurements of EVLW have been expected to be superior to blood oxygenation and chest radiography. They are based on the kinetics of one or two tracers injected centrally and measured in an artery. Initial techniques were based on a double-indicator dilution method. These techniques gained renewed attention with the introduction of a clinical device to assess EVLW using the transpulmonary thermodilution technology, which facilitated bedside measurements.[410] The device uses cold saline as the single indicator injected in a central venous line. EVLW and additional hemodynamic parameters (i.e., cardiac output) are computed from the curve of temperature in the peripheral artery.[411] Good reproducibility and correlation can occur with gravimetric methods and can be a useful clinical and research tool. EVLW may be a predictor of mortality in patients with severe sepsis[412] and ARDS.[413,414] It is a diagnostic tool in detecting early pulmonary edema,[415,416] including reperfusion edema after pulmonary endarterectomy,[417] after lung transplantation,[418] and in evaluating the effect of ventilatory modes during esophagectomy.[419] The measurement has also been proposed to guide fluid therapy in ARDS[420] and subarachnoid hemorrhage,[421] as well as assess the effect of steroids during cardiac surgery.[422] EVLW was the primary outcome variable in clinical trials to study the efficacy of salbutamol to resolve pulmonary edema in patients with ARDS (the Beta-Agonist Lung Injury Trial)[423] and lung resection.[424]

The limitations on this technique derive from the considerable and at times conflicting assumptions.[411,425] Measurement premises include that the thermal indicator reaches all lung regions and equilibrates in all of them and that the central circulation volumes between the injection and temperature measurement sites can be described as a small number of individual well-mixed compartments, each showing a monoexponential decay of temperature with time. Experimental evidence indicated that assumptions for the method do not apply to all conditions; an important factor is the changes in the regional distribution of perfusion during lung injury.[411,426,427] These changes may compromise the measurement.[425] Indeed, redistribution of lung perfusion can produce measurement changes larger than those seen in the Beta-Agonist Lung Injury Trial between treatment and control groups.[423,426] Such results are also consistent with the influence of the type of lung injury on the accuracy of EVLW measurements,[428-430] as well as with the poor correlation between transpulmonary thermodilution EVLW and computed tomographic estimates of EVLW.[431,432] Thus the expected reliability of transpulmonary thermodilution EVLW to follow trends[433] cannot be taken for granted, and it requires interpretation in light of potential simultaneous changes in regional perfusion. Finally, the technique requires placement of arterial and central venous catheters, thereby increasing invasiveness.

Renal Pathophysiology and Treatment for Perioperative Ischemia and Nephrotoxic Injury

KATHLEEN D. LIU, DANIEL H. BURKHARDT III, and RUPERT M. PEARSE

KEY POINTS

- The incidence of perioperative acute kidney injury (AKI) (previously referred to as acute renal failure) varies, depending on the definition used.
- Although uncommon, AKI requiring dialysis is associated with extremely high morbidity and mortality rates.
- The mechanism for perioperative AKI is complex and commonly involves multiple factors including ischemia-reperfusion injury, inflammation, and toxins.
- Repeated direct perioperative assessments of renal hemodynamics or tubular function are impractical; therefore indirect assessments, such as trends of serum creatinine concentrations, are the best practical perioperative tools to assess renal function.
- Intraoperative urine formation depends on many factors and is not validated as a measure of the risk of postoperative renal dysfunction. Yet postoperatively, patients with low intraoperative urine output may develop renal dysfunction. Therefore urine output should be carefully monitored in the intraoperative setting.
- Early biochemical markers for kidney injury may soon become new tests that can provide prompt clinical information.
- As part of preoperative risk assessment, both serum creatinine and proteinuria can provide important and useful information.
- Intraoperative hypotension and hypovolemia are significant risk factors for AKI.
- With regard to fluid management, the use of balanced salt solutions may reduce the risk of AKI. Volume overload is a risk factor for adverse outcomes in patients with AKI and may influence concentrations of conventional markers of kidney function such as serum creatinine.
- Renal replacement therapy may be indicated for severe AKI: at present, data does not support the use of one modality over another.

Introduction and Acute Kidney Injury Definitions

Acute kidney injury (AKI) (previously known as acute renal failure) is characterized by rapid decline in the glomerular filtration rate (GFR) and the accumulation of nitrogenous waste products (blood urea nitrogen [BUN] and creatinine). AKI occurs in approximately 5% to 25% of all hospitalized patients, depending on the precise definition used for AKI, and with more frequent rates in patients who are critically ill in the intensive care unit (ICU) (also see Chapter 17). AKI is also a serious perioperative complication for patients undergoing major surgery.[1-4] As the incidence of AKI varies by the definition used, the mortality of AKI ranges from 10% to 35% for mild AKI, whereas AKI in the ICU setting is associated with a 50% to 80% mortality rate. However, supportive care with dialysis has reduced mortality from AKI. Whereas the mortality rate of oliguric AKI was 91% during World War II, mortality declined to 53% during the Korean War with the provision of dialysis.[5] AKI requiring dialysis develops in 1% to 7% of patients after cardiac or major vascular surgery and is strongly associated with morbidity and mortality in this context.[6-9]

Perioperative renal failure was long defined as a requirement for postoperative dialysis. However, this concept has evolved during the past several years. First, because the implications of requiring postoperative dialysis are quite different for a patient starting with a normal baseline renal function compared with one starting with advanced chronic kidney disease and because the criteria for the use of dialysis are not standardized, the usefulness of dialysis alone to define AKI has been questioned. Second, studies are difficult to compare because of the use of nonstandard definitions for AKI. For example, in one review of 28 studies,[10] definitions for perioperative AKI varied. Third, consensus definitions that focus on small changes in serum creatinine and on

TABLE 42.1 Comparison of the RIFLE, AKIN, and KDOQI Consensus Criteria for Acute Kidney Injury

RIFLE		AKIN		KDIGO		
Class	**SCr**	**Stage**	**SCr**	**Stage**	**SCr**	**Urine Output**[a]
Risk	Increase in SCr to >1.5× baseline	1	Increase in SCr ≥0.3 mg/dL or to ≥1.5×-2× baseline	1	Increase in SCr ≥0.3 mg/dL within 48 h or to ≥1.5×-2× baseline, which is known or presumed to have occurred within the past 7 days	Urine output <0.5 mg/kg/h for >6 h
Injury	Increase in SCr to >2× baseline	2	Increase in SCr to >2×-3× baseline	2	Increase in SCr to >2×-3× baseline	Urine output <0.5 mg/kg/h for >12 h
Failure	Increase in SCr to >3× baseline, or increase of ≥0.5 mg/dL to absolute value of ≥4 mg/dL	3	Increase in SCr to >3× baseline, or increase of ≥0.5 mg/dL to absolute value of ≥4 mg/dL, or need for RRT	3	Increase in SCr to >3× baseline, or increase to absolute value of ≥4 mg/dL, or need for RRT; in pediatric patients eGFR <35 mL/min/1.73 m^2	Urine output <0.3 mg/kg/h for >12 h or anuria for >12 h
Loss	Need for RRT >4 weeks					
End stage	Need for RRT >3 months					

[a] Is common to all three consensus criteria.

The three consensus criteria use the same urine output criteria, but slight differences in the creatinine criteria are used to define AKI.

AKI, Acute kidney injury; *AKIN,* acute kidney injury network; *eGFR,* estimated glomerular filtration rate; *KDIGO,* kidney disease: improving global outcomes; *RIFLE,* risk, injury, failure, loss, end-stage disease; *RRT,* renal replacement therapy; *SCr,* serum creatinine.

changes in urine output to define AKI have received widespread adoption. This last conclusion is based on the recognition that small changes in renal function directly relate to an increased risk of death.[11]

As a result, recent consensus criteria are being used to define AKI in both the perioperative and other medical settings. The first proposed consensus criteria were the RIFLE (**R**isk, **I**njury, **F**ailure, **L**oss, **E**nd-stage) kidney disease criteria developed by the Acute Dialysis Quality Initiative (Table 42.1).[12] These have subsequently undergone two modifications by the Acute Kidney Injury Network[13] and in the Kidney Disease: Improving Global Outcomes (KDIGO) AKI guidelines.[14] As detailed in Table 42.1, the central components of these criteria are the focus on relative and absolute changes in creatinine from a baseline value and the definition of several degrees of AKI severity. Consequently, milder AKI (e.g., KDIGO, stage 1 disease) will be more common than stage 3 disease and will also be associated with a lower mortality rate. These criteria have also proposed definitions for AKI based on urine output. Overall, although there are studies demonstrating that AKI defined based on urine output is associated with adverse outcomes in the critical care setting and is more common than AKI defined based on creatinine,[15] the urine output criteria are not as well validated. At present, there is no clear method to correct urine output for morbid obesity; in addition, urine output may be unmeasurable if a urinary bladder catheter is not present.[16] Not surprisingly, AKI by urine output criteria is substantially more common than AKI by creatinine-based criteria; in a study of more than 4000 subjects undergoing major noncardiac surgery, the incidence of AKI increased from 8% to 64% when urine output criteria were incorporated.[17] Although each AKI stage was associated with an increased risk of death, the association with mortality was attenuated in this analysis when urine output criteria for AKI were used. Finally, it should be noted that the importance of oliguria (<0.5 mL/kg/h) as a predictor of creatinine-based AKI is less well established in the perioperative setting than in other clinical settings.[18,19] In a recent large single-center observational study, urine output of less than 0.3 mL/kg/h during major abdominal surgery was associated with an increased risk of perioperative AKI (defined as a 0.3 mg/dL rise in serum creatinine within 48 hours or a 50% increase over 7 days from baseline).[20] However, urine output within the 0.3 to 0.5 mL/kg/h range was not associated with creatinine-based AKI.

Additional challenges for the identification of AKI in the intraoperative setting include large blood volume loss and fluid shifts, which may artificially dilute serum creatinine. Unlike the postoperative or critical care setting where renal monitoring can involve periodic evaluation of kidney function under relatively stable conditions, intraoperative renal monitoring involves a briefer unstable period, often involving significant blood loss, major fluid shifts, wide hemodynamic fluctuations, and even direct compromise to renal artery blood flow. Therefore the anesthesia provider is likely the first monitor (in a sense) required for preserving renal function by recognizing and treating factors that may contribute to or exacerbate AKI; for example, the toxic effects of aminoglycosides and iodinated contrast materials are exacerbated by intravascular volume depletion.

As medical populations shift toward older and more critically ill patients undergoing increasingly high-risk procedures, patients are at an increased risk of AKI in the perioperative setting, and the role of the anesthesia provider becomes even more critical. Indeed, a recent study of dialysis after elective major surgery suggests that the incidence of dialysis-requiring AKI is rising from 0.2% in 1995 to 0.6% in 2009, with the majority of the increase occurring after vascular and cardiac surgery.[21] Although ischemic causes may be primarily responsible for perioperative AKI,[22,23] the successful development of renoprotective strategies has not occurred. Furthermore, other pathophysiologic contributors to perioperative AKI may include contrast-induced nephropathy, pigment nephropathy (e.g., hemoglobin, myoglobin), cholesterol emboli (e.g., atheroembolic renal disease), aminoglycoside toxicity, and sepsis. Animal studies of such pure nephropathies treated

Fig. 42.1 Procedural and patient factors related to surgery contributing to the risk of perioperative acute kidney injury (AKI) and postoperative morbidity and mortality. Of note, although AKI contributes to the risk of morbidity and mortality, a significant part of this association must also be attributed to other very serious conditions, such as sepsis, that can cause injury and are also major sources of adverse outcomes. (Modified from Stafford-Smith M, Patel U, Phillips-Bute B, et al. Acute kidney injury and chronic kidney disease after cardiac surgery. *Adv Chronic Kid Dis.* 2008;15:157–177. Used with permission.)

with logical renoprotective interventions often demonstrate success; unfortunately, this success has not extended to equivalent renoprotection in humans. It may not be surprising that a specific treatment for a pure nephropathy nonselectively applied to a mixture of nephropathies, variably expressed in different patients, would be unsuccessful. Postoperative AKI, rather than being a single entity, is likely a mosaic of several pure nephropathies, each of varying importance for a particular patient and procedure (Fig. 42.1).

Pathophysiologic Processes of Ischemic Acute Kidney Injury

In general, the causes for AKI can be divided into prerenal, intrinsic renal, and postrenal sources. In the perioperative setting, patients may be at increased risk for prerenal AKI, either attributable to volume depletion or to exacerbation of associated chronic prerenal physiologic conditions, such as congestive heart failure, which may be exacerbated by volume overload. Intraoperatively, hypotension due to vasodilation and negative inotropy/chronotropy from anesthetic agents may lead to prerenal physiology. Depending on the nature of the surgical procedure, the patient may also be at increased risk of postrenal AKI attributable to obstruction of the ureters, bladder, or urethra. However, the primary cause of perioperative AKI is *acute tubular necrosis* (ATN). Defining the cause of AKI is also critical because treatment of the underlying cause is critical for the reversal of AKI and potential renal recovery.

The two primary mechanisms of ATN are ischemia-reperfusion and nephrotoxic effects, with three sources of insult common to many surgical procedures during which postoperative AKI is prevalent: hypoperfusion, inflammation, and atheroembolism. Other sources of renal insult in selected patients may include rhabdomyolysis and specific drug-related effects. Certain classes of medications may also contribute to hypoperfusion by virtue of their hemodynamic effects (notably angiotensin-converting enzyme [ACE] inhibitor 1, angiotensin-receptor blockers [ARBs], and nonsteroidal antiinflammatory drugs [NSAIDs]), and, consequently, the risk of ATN.

Ischemic renal failure related to shock or severe dehydration is always preceded by an early compensatory phase of normal renal adaptation (e.g., pre-prerenal failure),

followed by a condition termed *prerenal azotemia* during which the kidney maximizes activities at the expense of the retention of nitrogenous end-products to preserve the internal environment through retention of solutes and water (Fig. 42.2). In studies of community-acquired AKI, the incidence of prerenal azotemia may be as frequent as 70%.[24] In contrast, in a classic study of hospital-acquired AKI, although hypoperfusion accounted for 42% of cases of AKI, only 41% of these cases of hypoperfusion were attributable to inadequate intravascular volume.[25]

Although prerenal azotemia is ominous and typically accompanied by oliguria (<0.5 mL/kg/h), it is reversible. At a critical tilting point, as conditions go beyond the compensatory mechanisms that maintain renal perfusion, ischemia leads to irreversible renal cell necrosis or ATN.[26] This represents the pure form of ischemic AKI. Other forms of ATN are due to toxins, including medications (e.g., aminoglycosides, cisplatinum), pigments (e.g., hemoglobin, myoglobin), and iodinated contrast dye. These forms of ATN do not involve the typical pattern of preceding prerenal azotemia with

associated oliguria, since the insult is sudden. Importantly, most cases of perioperative AKI are the result of numerous renal insults, rather than being attributable to one pure source (Fig. 42.3). In particular, patients with prerenal azotemia are likely at increased risk for toxic ATN.

Interruption of blood flow to the kidneys for more than 30 to 60 minutes results in ATN and irreversible cell damage. The kidneys receive 1000 to 1250 mL/min of blood or 3 to 5 mL/min/g of tissue for the average adult, and this amount far exceeds what is needed to provide the kidney's intrinsic oxygen requirement. Intracortical blood flow may not be evenly distributed.[27] Because the renal cortex contains most of the glomeruli and depends on oxidative metabolism for energy, ischemic hypoxia injures the renal cortical structures, particularly the pars recta of the proximal tubules. As ischemia persists, the supply of glucose and substrates continues to decrease; glycogen is consumed, and the medulla, which depends to a great extent on glycolysis for its energy sources, becomes more adversely affected. Early cell changes are reversible, such as the swelling of cell organelles, especially the mitochondria. As ischemia progresses, a lack of adenosine triphosphate interferes with the sodium pump mechanism, water and sodium accumulate in the endoplasmic reticulum of tubular cells, and the cells begin to swell. Onset of tubular damage usually occurs within 25 minutes of ischemia as the microvilli of the proximal tubular cell brush borders begin to change. Within an hour, they slough off into the tubular lumen, and membrane bullae protrude into the straight portion of the proximal tubule. After a few hours, intratubular pressure rises, and tubular fluid passively backflows. Within 24 hours, obstructing casts appear in the distal tubular lumen.

RENAL RESPONSE TO HYPOPERFUSION: AUTOREGULATION AND DISTRIBUTION OF CARDIAC OUTPUT TO THE KIDNEYS

A common intraoperative stress that puts patients at risk for AKI is hypoperfusion due to hypotension and/or hypovolemia. The fraction of cardiac output perfusing the kidneys depends on the ratio of renal vascular resistance to systemic vascular resistance.[26] In general, the response to renal hypoperfusion involves three major regulatory mechanisms that support renal function: (1) afferent arteriolar dilation increases the proportion of cardiac output that perfuses the kidney; (2) efferent arteriolar resistance increases the filtration fraction and preserves GFR; and (3) hormonal and neural responses improve renal perfusion by increasing intravascular volume, thereby indirectly increasing cardiac output.

The kidney produces vasodilator prostaglandins to counteract the effects of systemic vasoconstrictor hormones such as angiotensin II. In a state of low cardiac output when systemic blood pressure is preserved by the action of systemic vasopressors, RBF is not depressed because the effect of the vasopressors is blunted within the kidney. Studies using specific inhibitors of angiotensin II have shown that efferent arteriolar resistance largely results from the action of angiotensin II.[28] At low concentrations, norepinephrine has a vasoconstricting effect on efferent arterioles, indicating that the adrenergic system may also be important for maintaining the renal compensatory response.[29]

Reductions in cardiac output are accompanied by the release of vasopressin and by increased activity of the sympathetic nervous system and the renin-angiotensin-aldosterone system. These regulatory mechanisms to preserve RBF conserve salt and water. One study reported the normal response to hemorrhage in otherwise healthy patients, describing a 30% reduction in RBF with a decrease in mean perfusion pressure from 80 to 60 mm Hg.[30] Changes known to occur at the initiation of cardiopulmonary bypass (CPB) surgery include greater reduction in renal perfusion than systemic perfusion, loss of RBF autoregulation, and stress hormone and inflammatory responses known to be harmful to the kidney.[31,32] These effects may explain why the duration of CPB surgery independently predicts postcardiac surgery renal impairment.

Detection of Acute Kidney Injury

LABORATORY TESTS OF SERUM AND URINE AS MARKERS OF RENAL FUNCTION

Standard serum and urine markers of renal function are discussed in Chapter 17. It should be emphasized that at present, repeated serum creatinine determinations (relative or absolute changes), are most often used to identify AKI. An inherent limitation of almost all currently available tools to detect AKI is the obligate delay between the *onset* of AKI and the *diagnosis* of AKI. One striking difference between the management of AKI and acute myocardial infarction is the lack of early biomarkers for AKI in routine clinical practice to guide prompt recognition and intervention when tissue is threatened. Thus significant ongoing efforts are testing the value of early AKI biomarkers and of real-time measurement of GFR.

NOVEL (EARLY) BIOMARKERS OF ACUTE KIDNEY INJURY

Limited progress in the care for AKI has fueled an enormous interest in new early biomarkers.[33-36] Although a few of the new tools represent attempts to find a filtration marker that is better than creatinine (e.g., cystatin C), most novel AKI biomarkers take advantage of one of the three early consequences of AKI: (1) tubular cell damage, (2) tubular cell dysfunction, and (3) adaptive stress response of the kidney. The hope is that such biomarkers will allow timely AKI identification, diagnosis (e.g., prerenal azotemia vs. ATN), and prognosis. Some of the more promising biomarkers are presented here (Box 42.1).

BOX 42.1 Early Biomarkers of Acute Kidney Injury

Filtration-Based Markers of Renal Dysfunction

Cystatin C
β-trace protein
β-2 microglobulin

Biomarkers Reflecting Renal Tubular Cell Damage (Tubular Enzymuria)

α-Glutathione S-transferase
π-Glutathione S-transferase
β-*N*-Acetyl-β-D-glucosaminidase
γ-Glutamyl transpeptidase
Alkaline phosphatase
Sodium hydrogen exchanger isoform 3

Biomarkers Reflecting Renal Tubular Cell Dysfunction (Tubular Proteinuria)

α_1-Microglobulin
β_2-Microglobulin
Albumin
Retinol-binding protein
Immunoglobulin G
Transferrin
Ceruloplasmin
Lambda and kappa light chains

Biomarkers Reflecting Renal Tubular Cell Response to Stress

Neutrophil gelatinase–associated lipocalin
Urinary interleukin-18
Kidney injury molecule-1
Liver fatty acid–binding protein
Insulin-like growth factor binding protein 7
Tissue inhibitor of metallo-proteinase 2

New Filtration-Based Markers of Renal Dysfunction

Of the most novel filtration-based markers of renal dysfunction, the most advanced is cystatin C, a member of the cystatin superfamily of cysteine-proteinase inhibitors that is produced by all nucleated cells at a constant rate. Cystatin C has been clinically available for longer than 15 years and can be rapidly determined. Similar to creatinine, cystatin C accumulates in the circulation with renal impairment and can be used as a marker of glomerular filtration. Serum cystatin C has theoretical advantages over creatinine, particularly as an indicator of mild chronic kidney disease and its sequelae.[38] Several GFR estimating equations have been proposed, based on cystatin C alone or cystatin C and creatinine for use in chronic kidney disease.[39,40] Although these are commonly used in clinical research studies, in general these are not in widespread clinical use at present.

Although cystatin C outperformed creatinine in detecting AKI after cardiac surgery in some small studies,[41] this sensitivity has not consistently been the case. Indeed, a large multicenter prospective observational study of AKI after cardiac surgery suggested that serum cystatin C was less, not more, sensitive for the detection of AKI. This study, conducted by the Translational Research Investigating Biomarker Endpoints in Acute Kidney Injury (TRIBE-AKI) Consortium, prospectively enrolled more than 1200 adults undergoing cardiac surgery and has rapidly advanced the field of novel biomarkers in this context. Of note, the subset of patients who had AKI by cystatin C and creatinine had more frequent risk of dialysis and death than those who had AKI by creatinine alone.[42] Conditions such as malignancy, human immunodeficiency viral infection, or corticosteroidal or thyroid hormone therapy are associated with increased serum levels of cystatin C without changes in renal function. Other novel markers of filtration include β-trace protein and β-2-microglobulin; these markers may be novel markers of mortality in the general population, compared with creatinine-based eGFR.[42] However, the additional utility of these markers in estimating GFR above and beyond creatinine and cystatin C is unknown.

Biomarkers Reflecting Renal Tubular Cell Damage (Tubular Enzymuria)

Renal tubular cells contain enzymes that are highly specific to their location within the kidney and even tubule region. Under conditions of cellular stress, these enzymes are shed into the urine, making these potentially appealing markers of kidney dysfunction. These markers include α and π isomers of glutathione s-transferase (GST), which are cytosolic enzymes from proximal and distal tubular cells, respectively, and N-acetyl-β-D-glucosaminidase, a proximal tubule lysosomal enzyme. Of note, although enhanced urinary excretion of tubular enzymes can signal damaged tubular cells, it can also reflect an increased turnover of tubular cells or some other metabolic disturbance; thus the use of these markers may need to be applied with caution.

Biomarkers Reflecting Renal Tubular Cell Dysfunction (Tubular Proteinuria)

When small proteins are filtered by the glomerulus, binding and endocytic reuptake in the proximal tubule normally returns these substances to the body through a megalin-mediated transport system. So-called tubular proteinuria results from functional impairment of this process and the escape of small proteins into the urine. Endogenous low molecular weight proteins that are normally taken up in this way include β_2- and α_1-microglobulin, retinol-binding protein, lysozyme, ribonuclease, IgG, transferrin, ceruloplasmin, and lambda (λ) and kappa (κ) light chains. Appearance of any of these substances in the urine heralds abnormal proximal nephron function consistent with AKI. However, lysine and its analog (e.g., ε-aminocaproic acid, tranexamic acid) can cause a profound but reversible inhibition of low molecular weight protein reuptake[43] that is transient and apparently benign due to blocking renal-binding sites.[44,45]

Biomarkers Reflecting Renal Tubular Cell Response to Stress

Examples of markers that assess the response of the kidney to stress include neutrophil gelatinase–associated lipocalin (NGAL), kidney injury molecule–1 (KIM-1), liver fatty acid–binding protein, and interleukin-18 (IL-18). These have each been extensively reviewed in detail in recent literature.[33-36] Two markers of G1-cell cycle arrest have been shown to be upregulated in AKI, insulin-like growth factor–binding protein 7 (IGFBP-7) and tissue inhibitor of metalloproteinases–2 (TIMP-2).[46] A test that combines levels of IGFBP-7 and TIMP-2 has received U.S. Food and Drug Administration (FDA) clearance as a biomarker for the identification of patients at high risk of AKI.

NGAL is a protein with a critical role in iron scavenging. A transcriptome-wide interrogation for genes induced very early after renal ischemia identified NGAL as a protein generated by ischemic renal tubular cells.[47] Administration of exogenous NGAL in animal models attenuates renal injury.[48] Enthusiasm for NGAL as a biomarker of AKI was fueled by a study in pediatric patients who underwent cardiac surgery, suggesting that plasma and urinary NGAL could predict AKI before elevations in serum creatinine (Fig. 42.4).[49] Although increased NGAL levels are associated with adverse outcomes,[50,51] studies in the adult perioperative literature have not consistently shown NGAL to predict AKI before elevations in serum creatinine.

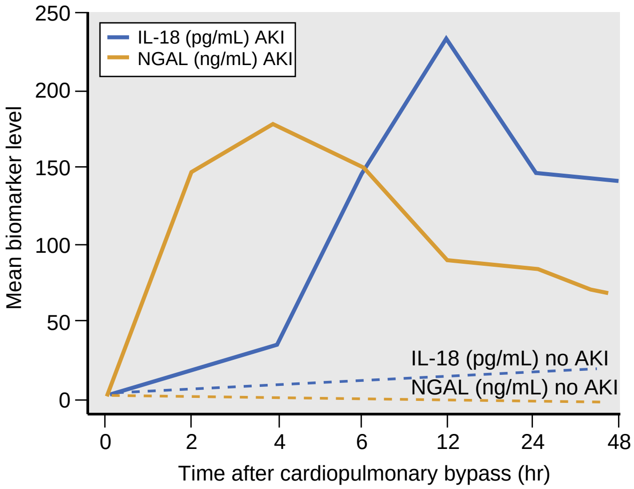

Fig. 42.4 Pattern of early biomarkers for urinary interleukin *(IL)*-18 and neutrophil gelatinase–associated lipocalin *(NGAL)* after cardiopulmonary bypass surgery in 55 patients with and without criteria for acute kidney injury *(AKI)* diagnosed 48 to 72 hours postoperatively (defined as a peak rise in serum creatinine concentration to >150% of baseline). (From Parikh CR, Mishra J, Thiessen-Philbrook H, et al. Urinary IL-18 is an early predictive biomarker of acute kidney injury after cardiac surgery. *Kidney Int*. 2006;70:199–203. Used with permission.)

KIM-1 is a transmembrane protein expressed at low levels under normal conditions that is significantly upregulated in proximal renal tubular cells in response to ischemic or nephrotoxic AKI.[52] In studies conducted by the Predictive Testing Safety Consortium, an academic-industrial partnership that has worked closely with the FDA to develop novel biomarkers of kidney injury for use in the preclinical setting (in particular, as markers of drug toxicity), KIM-1 outperformed a number of traditional markers of kidney injury in a variety of preclinical models.[53] More recently, assays have been developed to detect plasma KIM-1, which appears to correlate with urinary KIM-1 in the setting of both acute and chronic kidney disease.[54]

Finally, cell cycle arrest has been implicated in models of AKI; more recently, two proteins that induce cell cycle arrest, IGFBP-7 and TIMP-2, have both been shown in a multicenter study to predict the development of KDIGO stage 2 and 3 AKI in critically ill patients. In a validation cohort, these biomarkers had an impressive area under the ROC curve of 0.80 for subsequent AKI.[55] There has been tremendous interest in the use of these biomarkers for perioperative risk stratification,[56,57] with clinical trials enrolling patients based on elevated levels of IGFBP-7 and TIMP-2 (typically expressed as the product of these two biomarkers).[58]

Preoperative Evaluation of Renal Function and Risk Stratification

The greater the magnitude and duration of the surgical insult and the number of acute and chronic risk factors, the greater the likelihood of perioperative renal compromise and hence the need for preoperative identification of high-risk individuals.[58-61] Common risk factors for AKI include intravascular volume depletion, aminoglycoside use, radiocontrast dye exposure, use of NSAIDs, septic shock, and pigmenturia. ACE inhibitors and ARBs, respectively, may contribute to intraoperative hypotension and may exacerbate AKI in the setting of impaired hemodynamics (volume depletion, NSAID use). Patients with preexisting renal insufficiency are clearly at increased risk for AKI and should be identified in the perioperative evaluation through measurement of serum creatinine and urinalysis (to evaluate for albuminuria/proteinuria). Chronic kidney disease affects more than 10% of the United States population. Common risk factors for chronic kidney disease include advanced age, diabetes, and hypertension. The potential value of understanding the genetic makeup of patients has yet to be fully explored and is likely to be important. For example, several genetic polymorphisms known to affect inflammation and vasoconstriction demonstrate strong associations with AKI after cardiac surgery,[62] including the IL-6 572C and angiotensinogen 842C polymorphisms. In the future, identification of such polymorphisms may improve perioperative risk stratification.

Large multicenter epidemiologic studies have identified a relationship between markers of abnormal central aortic compliance, such as preoperative isolated systolic hypertension (>160 mm Hg) and wide pulse pressure hypertension (>40 mm Hg),[63,64] and postoperative AKI and dialysis, in particular in patients undergoing cardiac surgery. Pulse pressure is an index of the effects of large artery stiffness and the rate of pressure on propagation and reflection within the arterial tree. Early return of reflected arterial waves during late systolic rather than early diastolic pressure (from increased propagation velocity in stiff vessels) increases systolic blood pressure (i.e., afterload) and decreases diastolic blood pressure (i.e., perfusion pressure). Perfusion pressure and the risk of perioperative renal dysfunction are linked by the preexisting capacity of the vasculature to compensate for low pressure as it determines flow. Those with a predisposition to low flow attributable to abnormal central aortic compliance (e.g., those with wide pulse pressure) may represent patients who require higher pressure to maintain adequate flow and minimize renal risk compared with normotensive patients.

In the context of specific surgery types (e.g., cardiac surgery), perioperative risk prediction tools have been developed. In general, these tend to effectively identify low-risk populations, but discrimination for higher risk patients is more modest. This may reflect the fact that intraoperative factors play a major role in the pathogenesis of AKI in a vulnerable patient. In addition, a number of these risk prediction tools focus on dialysis-requiring AKI, which is only the "tip of the iceberg" with regard to disease burden.

Perioperative Acute Kidney Injury: Mechanisms and Treatment

As described in Chapter 17, anesthesia and surgery influence normal renal function primarily through changes in GFR and urine flow that are attributable to changes in blood pressure and cardiac output. Fluctuations in blood pressure have a major effect on RBF and glomerular filtration.[19,31,65] Here, we will briefly discuss considerations for several anesthetic techniques, followed by several specific perioperative considerations.

REGIONAL ANESTHESIA

Regional anesthetics and the kidneys interact in a complex manner that varies according to the underlying cardiovascular, renal, fluid, and electrolyte status of the patient.[66] In general, epidural and spinal anesthesia reduce systemic and renal vascular sympathetic tone.[67] Spinal cord segments T4 through L1 contribute to the sympathetic innervation of the renal vasculature, which is mediated by sympathetic fibers from the celiac and renal plexus.[67,68] Autonomic blockade above the fourth thoracic level also blocks cardioaccelerator sympathetic innervation to the heart. If neuraxial blockade reduces arterial blood pressure and cardiac output, then the RBF will be decreased with matching reductions in glomerular filtration and urine output.

Although controversial, intraoperative neuraxial blockade and postoperative epidural analgesia decrease rates of AKI. Rodgers and colleagues conducted a systematic review of 107 randomized clinical trials of intraoperative neuraxial blockade and demonstrated a 30% reduction in the odds of postoperative mortality.[69] This reduction was associated with decreases in the incidence of deep venous thrombosis, pulmonary embolism, transfusion, pneumonia, and respiratory depression, as well as renal failure, although the confidence limits for the renal failure estimates were very wide, in part due to the small number of cases of renal failure observed. Moraca and associates conducted a meta-analysis and reported on the association of thoracic epidural anesthesia with improved surgical outcomes attributable, in part, to a reduction of perioperative morbidity, including reductions in infection, ileus, blood loss, and AKI.[70] Other studies have examined the impact of epidural anesthesia during cardiac surgery and have suggested a benefit with regards to renal failure, although the confidence intervals were wide.[71] Unfortunately, renal failure was not an outcome of several recently published meta-analyses focused on epidural anesthesia during cardiac surgery.[72,73] Finally, with regard to postoperative analgesia, a recent Cochrane meta-analysis that focused on abdominal aortic surgery suggested better postoperative analgesia and a reduction in other complications including myocardial infarction and respiratory with epidural analgesia but no effect on AKI or postoperative mortality.[74]

EFFECTS OF INHALED ANESTHETICS

From a historic perspective, older volatile inhaled anesthetics including methoxyflurane and enflurane (no longer clinically used) when used for prolonged periods lead to significant generation of inorganic fluoride[74-77] and were associated with polyuric renal insufficiency. However, despite significant fluoride generation with sevoflurane and the generation of compound A (a metabolite associated with renal injury in experimental models), there is no reported association with AKI.[76] This may be due to the shorter duration of elevated fluoride levels with sevoflurane and the site of metabolism (intrarenal metabolism of methoxyflurane is fourfold greater than that of sevoflurane).

EFFECTS OF INTRAVENOUS ANESTHETICS

Propofol and dexmedetomidine may have antiinflammatory effects that are renoprotective. Propofol increases production of bone morphogenetic protein–7 (BMP-7), which suppresses the tumor necrosis factor α–induced inflammatory cascade during sepsis-induced AKI,[78] as well as decreased injury during ischemia-reperfusion[79,80] and unilateral ureteral obstruction.[81] Similarly, in addition to altering RBF and sodium and water handling, the α_2-adrenoreceptor agonists such as dexmedetomidine may stimulate BMP-7 production in the setting of sepsis and ischemia-reperfusion.[81-84] There has been significant interest in the use of dexmetomidine, in particular in the setting of cardiac surgery, with a recent meta-analysis suggesting a reduction in postoperative AKI with the use of dexmetomidine (OR 0.65; 95% confidence interval [CI], 0.45-0.92, $P = .02$).[85]

SPECIFIC PERIOPERATIVE PERTURBATIONS AND RENAL FUNCTION

Several surgical interventions can affect RBF and, consequently, renal function. Whereas aortic cross-clamping above the renal arteries has obvious influence on glomerular filtration, infrarenal aortic cross-clamping and unclamping also have significant indirect effects on glomerular filtration and urine formation through changes in myocardial function, sympathetic activity, neuronal and hormonal activity (e.g., renin and angiotensin production), intravascular volume, and systemic vascular resistance.[86] During standard CPB surgery, cardiorenal relationships are approximately as expected; RBF decreases to 12% to 13% of total pump flow and is predicted by flow rate and perfusion pressure; however, only mean pressure correlates with urine output.[31,87]

AKI after aortocoronary bypass surgery continues to be a devastating complication that is associated with multiorgan dysfunction, increased resource utilization, high cost, and increased mortality. Annually, approximately 350,000 patients in the United States undergo coronary artery bypass graft (CABG) surgery. In a multicenter observational study focused on AKI after cardiac surgery, 5% of participants developed AKI as defined by the need for acute dialysis or a doubling of serum creatinine from baseline.[88] The mechanism of perioperative AKI during cardiac surgery is multifactorial. Significant risk factors for AKI include underlying patient characteristics, such as age older than 75 years, history of diabetes, hypertension, pulse pressure, ventricular dysfunction, myocardial infarction, renal disease, perioperative medication exposures (e.g., aprotinin, hetastarch), and surgical characteristics such as intraoperative use of multiple inotropes, insertion of intraaortic balloon pump, and extended duration of the CPB surgery.[63,89-92]

The role of CPB surgery in postoperative AKI remains controversial. In their comprehensive guidelines on AKI, KDIGO reviewed the literature on postoperative AKI between patients undergoing off-pump and on-pump coronary revascularization surgeries and ultimately recommended that "off-pump CABG surgery not be selected solely for the purpose of reducing perioperative AKI or need for renal replacement therapy (RRT)."[14] However, patients with chronic kidney disease, who are at the highest risk for AKI after CPB surgery, have often been excluded from randomized clinical trials of off-pump versus on-pump CABG. For example, in the Randomized On/Off Bypass (ROOBY) trial, in which 2303 patients were randomized to off-pump versus on-pump CABG, approximately 7.5% of patients had a preoperative serum creatinine level ≥1.5 mg/dL.[93]

A large observational study of 742,909 nonemergent, isolated CABG cases (including 158,561 off-pump cases) from the Society of Thoracic Surgery Database suggests a benefit to off-pump CABG in those with chronic kidney disease.[94] Propensity methods were used to adjust for patient- and center-level imbalances. The primary endpoint was death or dialysis. In those with lower estimated GFR (eGFR), the risk difference (i.e., number of patients with the outcome per 100 patients in those who underwent CPB minus the number with the outcome in those who underwent off-pump CABG) for the primary endpoint was 0.66 (95% CI, 0.45-0.87) for eGFR 30 to 59 mL/min/1.73 m^2 and 3.66 (95% CI, 2.14-5.18) for eGFR 15 to 29 mL/min/1.73 m^2. Both component endpoints followed the same trend. Highlighting the importance of chronic kidney disease as a risk factor for AKI after cardiac surgery, whereas slightly less than 1% of the overall cohort received dialysis after cardiac surgery, 2% of those with eGFR 30 to 59 mL/min/1.73 m^2 and 12.5% of those with eGFR 15 to 29 mL/min/1.73 m^2 required dialysis. The risk difference for dialysis alone in the same groups was 0.47 (95% CI, 0.31-0.62) and 2.79 (95% CI, 1.37-4.20) with on-pump versus off-pump CABG, respectively (Fig. 42.5). Along the same lines, a 2932 patient-substudy of the CORONARY clinical trial followed patients after off- or on-pump CABG surgery and demonstrated an interaction between preoperative chronic kidney disease (defined as eGFR <60 mL/min/1.73 m^2) and AKI (defined as a 50% increase in serum creatinine from prerandomization baseline within 30 days). In those with chronic kidney disease, 19.2% of those in the off-pump arm had AKI, compared to 30.2% in those who had on-pump surgery. However, there was no difference in sustained renal dysfunction, defined as a 20% or greater loss in eGFR at 1 year between the two study arms (17.1% vs. 15.3% in the off- vs. on-pump arms, $P = .23$). However, when those with AKI were compared to those who did not have AKI (regardless of treatment arm), AKI was independently associated with an increased risk of sustained renal dysfunction, with an adjusted odds ratio of 3.37 (95% CI, 2.65-4.28, $P < .001$.[95] This study highlights the fact that in the setting of chronic kidney disease, AKI is only one of many risk factors for chronic kidney disease progression.

In the setting of CABG, there has been tremendous interest in prevention of AKI, and numerous pharmacologic interventions have been tested. As stated previously, one of the major challenges for AKI prevention is that both pre- and intraoperative factors impact the risk of AKI, so it is difficult to identify a priori those who are at highest risk of AKI. Interventions of recent interest where there is not a sufficient evidence base for wide-spread adoption include remote ischemic preconditioning, atrial natriuretic peptide, and fenoldopam, among others.[96,97]

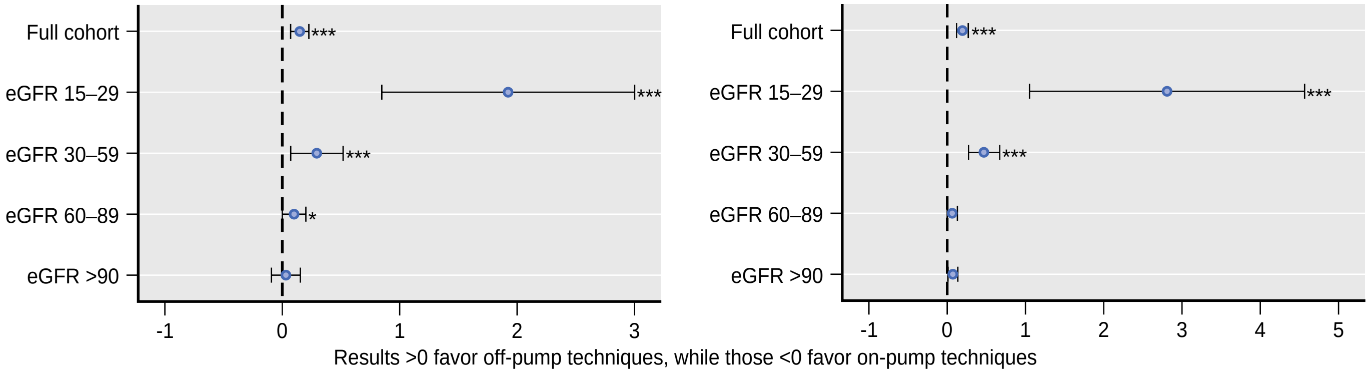

Fig. 42.5 Estimates of adverse outcomes associated with on-pump versus off-pump coronary artery bypass grafting by baseline estimated glomerular filtration rate *(eGFR)*. For both mortality *(left panel)* and renal replacement therapy *(right panel)*, off-pump CABG techniques appear to confer a benefit in those with lower eGFR. $^*P < .05$, $^{**}P < .01$, $^{***}P < .001$. (Redrawn from Chawla LS, Zhao Y, Lough FC, et al. Off-pump versus on-pump coronary artery bypass grafting outcomes stratified by preoperative renal function. *J Am Soc Nephrol.* 2012;23:1389–1397.)

INTRAOPERATIVE MANAGEMENT FOR AKI PREVENTION: OXYGEN DELIVERY: BLOOD GAS, ACID-BASE BALANCE, AND HEMATOCRIT

Severe arterial hypoxemia to a partial arterial pressure of oxygen (PaO_2) value of less than 40 mm Hg is associated with decreased RBF and renal vasoconstriction.[98,99] Inequalities in oxygen supply and demand are exaggerated and medullary hypoxia is extreme during CPB, effects that last well beyond separation from circulatory support in experimental models.[100]

The effects of anemia on the kidney have been studied mostly in the context of CPB management. When crystalloid and colloid solutions are used to prime an extracorporeal circuit, the initiation of CPB surgery obligates an acute decrease of approximately 30% in oxygen-carrying capacity. Animal studies endorse moderate hemodilution (hematocrit 20% to 30%) as renoprotective during CPB surgery through a reduction of blood viscosity and improved regional blood flow.[101] However, although hematocrit values less than 20% during CPB surgery are commonly accepted clinically (extreme hemodilution), very low hematocrit values are linked with adverse outcomes, including AKI.[102-104] The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists guidelines suggest that transfusion triggers should be lower during CPB surgery and that a transfusion trigger of 6 g/dL is reasonable, except in those at risk for end-organ ischemia, in whom a higher trigger may be reasonable.[105] More recently, the European Association for Cardio-Thoracic Surgery and the European Association of Cardiothoracic Anesthesia have developed comprehensive guidelines and suggest that a target hematocrit of 21% to 24% during cardiopulmonary bypass is reasonable.[106]

The solution may not be as simple as transfusion because blood transfusions themselves have been linked to AKI. In a systematic review, Karkouti found 22 studies that examined the association between blood transfusions and AKI postcardiac surgery. An independent association between transfusions and AKI was found in 18 of the 22 studies.[107] The association of perioperative anemia with AKI was further examined in 14 studies, and 9 of the studies found an independent association of perioperative anemia with AKI. Proposed mechanisms for transfusion-associated AKI include exacerbation of inflammation and oxidative stress, which occur during the CPB surgery.

There has been tremendous interest in the impact of the age of stored blood on the risk of AKI. Old blood may result in higher circulating levels of free hemoglobin and free iron, and there has been interest in the impact of the “storage lesion” on AKI. However, at present, data does not support the selective use of fresh blood in the perioperative setting to reduce the risk of AKI.[108-110]

Perioperative Blood Pressure and Fluid Management

There has been significant interest in perioperative blood pressure targets and the impact on AKI. Several large observational cohort studies have suggested that even transient hypotension was associated with postoperative AKI.[111-115] One prospective randomized trial compared an individualized blood pressure management strategy targeted at maintaining systolic blood pressure within 10% of baseline versus a standard management strategy (treatment of systolic blood pressure <80 mm Hg or lower than 40% from baseline) and demonstrated a significant reduction in the primary composite endpoint (systemic inflammatory response and at least one organ dysfunction within 7 days). This modest sized clinical trial demonstrated a nonsignificant trend toward reduced postoperative AKI in the individualized blood pressure management arm.[116] Thus blood pressure targets, in particular in patients with chronic kidney disease, need to take into consideration preoperative blood pressure.

Intravascular volume depletion, which commonly occurs in fasting patients undergoing surgery, is a risk factor for AKI. For example, the combination of diabetes mellitus and intravascular volume depletion increases the chance of developing AKI by 100-fold.[117] The most practical preoperative methods to assess volume status are with preoperative patient history and physical examination and by assessing changes in arterial blood pressure in response to changing conditions and dynamic maneuvers. For example, an awake patient normally does not have significant orthostatic changes in arterial blood pressure unless an autonomic or intravascular volume deficit exists. During anesthesia, a similarly dehydrated patient may demonstrate paradoxical arterial pulse changes with positive-pressure inspiration. Nonetheless, there has been tremendous interest in the use of intravascular monitoring techniques in the perioperative setting to reduce the risk of AKI.

The decision to use any monitor should depend on the patient's functional cardiac reserve status and the extent of the proposed surgical insult. Although maintaining adequate cardiac output is necessary for maintaining adequate RBF, adequate flow may still not occur. The use of intravascular volume monitoring techniques must include cautious identification of physiologic conditions that influence their validity as a reflection of preload in a particular patient. For example, monitoring central venous pressure to assess preload involves assumptions about normal left and right ventricular function; pulmonary vascular resistance; and mitral, pulmonary, and tricuspid valve function. Similarly, monitoring pulmonary artery pressure or pulmonary capillary wedge pressure assumes normal left ventricular compliance, mitral valve function, and normal airway pressure.

Direct measurements of left atrial pressure may offer insight into the kidney pressure-flow relationship because left atrial hypotension is a powerful stimulus for renal vasoconstriction. Despite equivalent reductions in cardiac output and arterial blood pressure, RBF decreases significantly more when left atrial pressure is decreased (e.g., hemorrhagic shock), compared with left atrial pressure when it is increased (e.g., cardiogenic shock).[118] Left atrial pressure receptors modulate renal vasoconstriction through the release of ANP, a hormone secreted by the cardiac atria in response to intravascular volume expansion.[119] ANP acts on the arterial and venous systems, the adrenal glands, and the kidneys to reduce intravascular volume and decrease blood pressure.[120] Within the kidney, the hormone increases hydraulic pressure in the glomerular capillaries through afferent arteriolar dilation and efferent arteriolar vasoconstriction. ANP reduces arterial blood pressure by relaxing smooth muscle and reducing sympathetic vascular stimulation and also inhibits renin and aldosterone secretion, causing renal vasodilation, natriuresis, and diuresis.

Despite the direct relationship of left atrial pressure and renal vasoconstriction, static monitors of intravascular volume status are gradually being replaced by echocardiographic and dynamic monitors of intravascular volume status. Intraoperatively, one of the most direct ways to monitor intravascular volume may be by direct assessment of the left ventricular end-diastolic area with transesophageal echocardiography. However, monitoring with invasive devices, such as pulmonary artery catheters, arterial cannulas, and transesophageal echocardiography, has not been demonstrated to reduce the incidence of AKI.

Guided fluid optimization has recently garnered significant interest as a step beyond traditional, somewhat unreliable guides to fluid administration (e.g., central venous pressure).[121,122] The principle behind fluid optimization is to maximize tissue-oxygen delivery by achieving a maximum stroke volume. Intravascular fluid management is typically guided by the physiologic response to dynamic measures; proposed measures include systolic pressure variation, pulse pressure variation, continuous cardiac output monitoring, and esophageal Doppler ultrasonography fluid boluses.[123] Some maneuvers to assess fluid responsiveness may be feasible in the critical care setting but not in the perioperative setting (e.g., passive leg raise).

Given the improved outcomes in patients who are critically ill with the acute respiratory distress syndrome and are managed with a restrictive fluid management strategy,[124] fluid restriction in the perioperative setting has gained attention. A meta-analysis of seven randomized clinical trials in the setting of intraabdominal surgery suggested a restrictive fluid strategy offered no benefit; however, there was also no evidence of harm, including AKI.[125] In some studies, excessive fluid restriction was associated with harm, including an increased risk of anastomotic breakdown and sepsis, and should clearly be avoided.[126] However, more recently, the RELIEF clinical trial randomized 3000 patients undergoing major abdominal surgery to a restrictive or liberal fluid strategy during surgery and up to 24 hours afterward; the restrictive fluid strategy was designed to provide a net even fluid balance.[127] There was no difference in the primary endpoint of disability-free survival at 1 year. However, the restrictive fluid strategy was associated with an increased rate of AKI (8.6% vs. 5.0%, $P < .001$) and surgical site infections (16.5% vs. 13.6%, unadjusted $P = .02$), though the comparison for surgical site infections was not considered significant after adjustment for multiple comparisons. Thus at present, fluid management strategies should avoid markedly positive fluid balance, but also need to be wary of underresuscitation.

There has been considerable interest in the use of balanced salt solutions instead of chloride-rich solutions to prevent AKI; the rationale is that chloride-rich solutions reduce renal perfusion in animal models.[128] Subsequently, a pre-post study of chloride-rich versus balanced salt solutions demonstrated a reduced incidence of stage 2 and 3 AKI during the balanced salt solution period.[129] Similarly, a propensity-matched study of patients undergoing major abdominal surgery suggested that patients who received balanced salt solutions had fewer postoperative complications, including postoperative dialysis.[130] However, a subsequent clinical trial, the SPLIT trial, suggested that there was no decrease in AKI with the use of Plasma-Lyte 148 in ICU patients.[131] Of note, 72% of the trial population was enrolled after surgery, with 49% enrolled after cardiac surgery. More recently, the SALT-ED and SMART trials were pragmatic clinical trials that randomized patients to receive balanced salt solutions or normal saline in alternating months in the Emergency Department and Intensive Care Units, respectively, at a single clinical center.[132,133] Both studies demonstrated a statistically significant reduction in the rate of major adverse kidney events at 30 days, a composite endpoint of death, dialysis, and persistent doubling of creatinine. In SMART, approximately 20% of subjects were admitted in the postoperative setting; there was no evidence of an interaction between treatment effect and type of ICU, but the study was underpowered to observe a difference within this subgroup.

Finally, are these solutions safe in patients who are prone to hyperkalemia? Because balanced salt solutions contain a physiologic amount of potassium, there has been concern that the administration of balanced salt solutions might lead to hyperkalemia in patients with reduced renal function. However, in two randomized clinical trials of intraoperative fluid selection in end-stage kidney disease patients undergoing kidney transplantation, there was no increase in the incidence of hyperkalemia.[134] The median volume of intravenous solution administered in a the trial that compared normal saline to an acetate based buffer was 2625 mL (IQR 2000-3001 mL);[135] in a trial comparing normal saline to lactated Ringers, mean fluid volumes were 6.1 ± 1.2 L and 5.6 ± 1.4 L, respectively.[136] Thus at reasonable doses, balanced salt solutions appear safe across a wide variety of patient populations and are associated with a decreased risk of AKI.

EXCESSIVE INTRAVASCULAR VOLUME AND THE ABDOMINAL COMPARTMENT SYNDROME

The abdominal compartment syndrome was first defined in 1985; since then, it has been progressively recognized as a common contributor to renal dysfunction in the setting of excessive intravascular volume.[137-139] Not surprisingly, excessive intravascular volume and mechanical ventilation with high airway pressures are significant contributors to the abdominal compartment syndrome. Abdominal compartment syndrome is defined as a sustained increase in intraabdominal pressures to greater than 20 mm Hg that causes organ dysfunction; in contrast, intraabdominal hypertension is typically defined as intraabdominal pressures ≥12 mm Hg without organ dysfunction. This increase in intraabdominal pressure decreases abdominal perfusion pressure (which is mean arterial pressure − intraabdominal pressure), and results in a functional prerenal state attributable to reduced renal perfusion.

The intraabdominal pressure can easily be measured using an indwelling Foley catheter and the same pressure tubing setup used for arterial line blood pressure monitoring.[140] The Foley catheter is clamped distal to the instillation port, and up to 25 mL of saline is instilled into the bladder. The transducer should be zeroed at the midaxillary line, and the pressure should be measured at end-expiration approximately 30 to 60 seconds after fluid is instilled into the bladder to allow for detrusor muscle relaxation. Of note, intraabdominal pressure may be chronically elevated to as high as 12 mm Hg in the obese adult but is not associated with end-organ dysfunction in this context.[141] Prompt recognition of the abdominal compartment syndrome and treatment via decompression in the appropriate clinical context is critical.

Nephrotoxins and Acute Kidney Injury

Recently, there has been significant controversy regarding the impact of iodinated contrast on AKI, with a number of observational studies suggesting that at a population level, iodinated contrast is not associated with an increased risk of AKI.[142,143] However, iodinated contrast is associated with intense renal vasoconstriction and causes significant AKI in the vulnerable subject. There has been significant interest in pharmacologic prevention of contrast-associated AKI. Clinical trials have demonstrated that pharmacologic interventions, including fenoldopam, n-acetyl-cysteine, and sodium bicarbonate, do not reduce the incidence of contrast-associated AKI.[144,145] Volume depletion and concomitant exposure to other nephrotoxins are key, preventable risk factors for AKI.

Other nephrotoxins commonly encountered in the perioperative setting include aminoglycosides and NSAIDs. In addition, there has been increasing interest in antibiotic nephrotoxicity. Specifically, the combination of vancomycin and piperacillin-tazobactam has been associated with an increased rate of AKI.[146] When possible, avoiding combinations of nephrotoxins is likely beneficial for AKI prevention.[147]

Renal Replacement Therapy

Despite best supportive care, at times, AKI progresses, and RRT is indicated. Conventional indications for dialysis include acidosis, electrolyte abnormalities (in particular, hyperkalemia), ingestions, volume overload, and uremia. There has been considerable interest in the optimal timing of dialysis initiation in critically ill and postoperative patients. A provocative, single-center study suggested that after cardiac surgery, there was significant benefit to initiation of dialysis for stage 2 AKI (doubling of sCr from baseline or urine output <0.5 mL/kg/h for 12 hours) versus waiting until stage 3 AKI (tripling of sCr from baseline, sCr ≥4 mg/dL with an acute rise of ≥0.5 mg/dL, or urine output <0.3 mL/kg/h for 24 hours).[148] Early RRT was associated with a lower incidence of death (39.3% vs. 54.7%, $P = .03$) and a greater rate of renal recovery at 90 days (53.6% vs. 38.7%, $P = 0.02$). It should be noted 90% of patients in the delayed arm received RRT, and the median difference in time to dialysis initiation was only 21 hours, so this is a remarkably large effect size that should be interpreted with caution. This study is in marked contrast to two large randomized clinical trials in critically ill patients suggesting that dialysis can be safely delayed in a number of patients.[149,150] In these clinical trials, patients were randomized to receive dialysis when they met criteria for stage 3 AKI or to initiate dialysis only after prespecified electrolyte/metabolic criteria were met or after AKI exceeded a prespecified duration. There was no difference in mortality between the two treatment arms; in addition, a significant proportion of subjects in the delayed therapy arm recovered and never required dialysis (29% in the IDEAL-ICU trial). Additional clinical trials are ongoing to further test the hypothesis that in critically ill patients, dialysis can be safely delayed.[151]

There has also been considerable interest in dialysis modality and the impact on outcomes. At present, four modalities of dialysis are possible in the ICU. Peritoneal dialysis requires placement of a catheter in the intraabdominal space; this is typically performed laparoscopically, but can be inserted at the bedside if needed. Dextrose-containing fluids drive fluid and solute removal. Thus a significant risk of peritoneal dialysis is infection (e.g., peritonitis). Furthermore, this modality cannot be used in patients who have had recent intraabdominal surgery, so in general, its role is quite limited in the perioperative setting, with the exception of patients who are maintained on this therapy for end-stage renal disease preoperatively. With regard to hemodialysis, modalities are typically divided into: intermittent hemodialysis (IHD), prolonged intermittent RRT (PIRRT)/slow low efficiency dialysis (SLED), and continuous renal replacement therapies (CRRT). As the name implies, IHD is typically performed over a 3- to 4-hour period, 3 to 6 days/week. PIRRT/SLED is typically performed over 6 to 12 hours/day, 3 to 6 days/week; there is no standard dialysis machine for PIRRT/SLED so dialysis programs may use this therapy quite differently. CRRT is performed on a continuous, 24 hours/day basis.

With regard to modality and outcomes, it has been specifically hypothesized that intradialytic hypotension might prolong AKI and delay renal recovery. However, no randomized clinical trials have demonstrated clear benefit to continuous RRT with regards to mortality or renal recovery.[152] Clinical trials have also examined the impact of dialysis dose and membrane on outcomes. These studies have established that there is a minimum dose of dialysis that should likely be measured and delivered,[153,154] and that modern dialysis membranes are all relatively biocompatible and there is no benefit of one membrane over another.

To maintain circuit patency, anticoagulation is often needed. At present, the two most common forms of anticoagulation are low-dose heparin (100 to 500 units/h) and regional citrate. In both cases, the anticoagulant is infused prefilter to minimize systemic effects. Even though the goal of heparin anticoagulation is to not affect systemic coagulation parameters such as partial thromboplastin time, there is a small increase in bleeding risk.[155,156] The goal of regional citrate anticoagulation is to reduce the ionized calcium concentration in the dialysis filter, since calcium is a required cofactor in the coagulation cascade. Thus citrate is infused prefilter and titrated to maintain a low postfilter ionized calcium. One of the challenges in the United States to the routine use of citrate anticoagulation is the lack of a citrate solution approved by the Food and Drug Administration for use with RRT; thus each center typically has developed its own protocol for titration and monitoring. That said, regional citrate anticoagulation is typically recommended in favor of other forms of anticoagulation.[14,155,156]

Occasionally, RRT is indicated in the operating room, typically during prolonged cases with significant blood product transfusion (e.g., liver transplantation). Close coordination between the nephrologist and the anesthesiologist is needed.

Summary

In patients with or at risk for developing AKI, perioperative management continues to be challenging. Numerous factors contribute to the heterogeneous condition referred to as perioperative AKI, but insults collectively combine through ischemic and toxic mechanisms. Recent research efforts directed to the investigation of AKI will likely lead to rapid developments in the field of renal function monitoring. At present, serum creatinine continues to be the mainstay of most renal function monitoring strategies, along with urine output. Best supportive care for perioperative AKI includes preoperative risk stratification with quantitation of serum creatinine and proteinuria/albuminuria for moderate-high risk surgeries, avoidance of hypotension and hypovolemia, along with judicious use of nephrotoxins. In the setting of severe AKI, support with RRT may be needed. At present, the timing of dialysis initiation is controversial, but early initiation does not appear to be associated with improved outcomes in critically ill patients.

Acknowledgment

The editors, publisher, and authors, Drs. Kathleen D. Liu, Daniel H. Burkhardt III, and Rupert M. Pearse, would like to thank Drs. Mark Stafford-Smith and Andrew Shaw for their contribution to this chapter in the prior edition of this work. It has served as the foundation for the current chapter.

43 Neuromuscular Monitoring

CASPER CLAUDIUS and THOMAS FUCHS-BUDER

KEY POINTS

- Good evidence-based practice dictates that clinicians always quantitate the extent of neuromuscular block by objective monitoring.
- The neuromuscular block should be adjusted to ensure optimal surgical conditions. In most procedures, one or two responses to train-of-four (TOF) stimulation will suffice. To avoid involuntary diaphragmatic movements, a deeper level of neuromuscular block is required (i.e., one to five responses to post-tetanic count [PTC]).
- Adequate recovery of postoperative neuromuscular function cannot be guaranteed without objective neuromuscular monitoring.
- Objective neuromuscular monitoring is essential for management of neuromuscular blockade intraoperatively and its reversal for postoperative care. Muscle relaxants should not be given in the intensive care unit without proper monitoring.
- It is impossible to exclude with certainty clinically significant residual neuromuscular block by clinical evaluation of recovery of neuromuscular function.
- Residual postoperative neuromuscular block causes decreased chemoreceptor sensitivity to hypoxia, functional impairment of the pharyngeal and upper esophageal muscles, impaired ability to maintain an open upper airway, and an increased risk of hypoxemic events, as well as the development of postoperative pulmonary complications.
- Absence of tactile fade in the response to TOF stimulation, tetanic stimulation, and double-burst stimulation does not exclude significant residual block.
- To exclude clinically significant residual neuromuscular block, the TOF ratio must exceed 0.9 when measured mechanically or electromyographically and 1.0 when measured acceleromyographically.
- Antagonism of the neuromuscular block with a cholinesterase inhibitor should not be initiated before at least two to four responses to TOF stimulation are observed.
- Antagonism of the neuromuscular block achieved by rocuronium and vecuronium can be initiated at all levels of block with the selective relaxant binding agent sugammadex.
- If adequate recovery (TOF ≥0.9-1.0) has not been documented objectively at the end of the surgical procedure, the neuromuscular block should be antagonized.

Our understanding of the pathophysiologic consequences of residual paralysis has improved over the last decades, and it is now generally accepted that even small degrees of residual paralysis (i.e., a train-of-four [TOF] ratio 0.7-0.9) may be clinically harmful.[1-4] As a consequence, the benchmark of adequate neuromuscular recovery has been revised several times; an adductor pollicis TOF ratio of 0.9 or greater is now required to exclude relevant residual neuromuscular block (i.e., paralysis). Clinically significant residual paralysis cannot be excluded using clinical criteria and it can persist postoperatively.[5,6] Objective monitoring of the degree of neuromuscular block associated with pharmacologic reversal reduces the incidence of residual paralysis and should be part of standard perioperative monitoring when neuromuscular blocking agents (NMBAs) are used.[7-13]

In awake patients, muscle power can be evaluated by tests of voluntary muscle strength, but this is impossible during anesthesia and recovery from anesthesia. Historically, anesthesiologists have used clinical tests to assess muscle power directly and to estimate neuromuscular function indirectly (muscle tone; feel of the anesthesia bag as an indirect measure of pulmonary compliance, tidal volume, and inspiratory force). All these tests are influenced by factors other than the degree of neuromuscular block and, therefore, should not be used to evaluate recovery from neuromuscular blockade. Whenever precise information regarding the status of neuromuscular functioning is desired, the response of muscle to nerve stimulation should be assessed. This procedure also takes into account the considerable variation in individual response and sensitivity to muscle relaxants.

This chapter reviews the basic principles of neuromuscular monitoring and the requirements for effective use of nerve stimulators for peripheral nerve stimulation. It also describes the response to nerve stimulation during depolarizing (phase I and phase II) and nondepolarizing neuromuscular block, provides information about the level of neuromuscular blockade, and discusses the consequences of residual paralysis. Moreover, methods of evaluating evoked neuromuscular responses with and without the availability of recording equipment are discussed.

Principles of Peripheral Nerve Stimulation

Neuromuscular monitoring is used to evaluate the effect of a NMBA. The muscle response after stimulation of its corresponding motor nerve is assessed. The most frequently assessed nerve-muscle unit is the ulnar nerve and the adductor pollicis muscle. The muscle response can be evaluated either qualitatively with a peripheral nerve stimulator or quantified with objective monitors. With the peripheral nerve stimulator, the observer evaluates the muscle response either tactically or visually, whereas with the monitor the response is objectively measured and displayed on a screen. Whatever method is used for neuromuscular monitoring, the clinician should be familiar with the following terms: supramaximal stimulation, calibration, impedance, and safety margin.

SUPRAMAXIMAL STIMULATION

The reaction of a single muscle fiber to a stimulus follows an all-or-none pattern. In contrast, the response (the force of contraction) of the whole muscle depends on the number of muscle fibers activated. If a nerve is stimulated with sufficient intensity, all fibers supplied by the nerve will react, and the maximum response will be triggered. After administration of a neuromuscular blocking drug, the response of the muscle decreases in parallel with the number of fibers blocked. The reduction in response during constant stimulation reflects the degree of neuromuscular block.

For the preceding principles to work, the stimulus must be truly maximal throughout the whole period of monitoring; therefore, the electrical stimulus applied is usually at least 15% to 20% greater than that necessary for a maximal response. For this reason, the stimulus is said to be supramaximal. This compensates for potential changes in skin resistance intraoperatively and assures constant maximal stimulation throughout the procedure.

However, supramaximal electrical stimulation can be painful, which is not a concern during anesthesia, but during recovery the patient may be awake enough to experience the discomfort of nerve stimulation. Therefore, some researchers advocate stimulation with submaximal current during recovery. Although several investigations indicate that testing of neuromuscular function can be reliably performed postoperatively with submaximal stimulation,[14,15] the accuracy of such monitoring is unacceptable with that low current.[15]

CALIBRATION

A device used for objective monitoring of the neuromuscular function should be calibrated before the NMBA is administered. Calibration adjusts the gain of the device to ensure that the observed response to supramaximal stimulation is within the measurement window of the device and as close as possible to the "100% control response." The calibration procedure varies with the type of device used, but most often it is done with 1.0 Hz single-twitch stimulation. It is especially important to calibrate when the onset and recovery of the neuromuscular block are established with single-twitch stimulation.

In the TOF mode of nerve stimulation, calibration is considered less important because all four responses are amplified equally. Consequently, the TOF ratio is rarely influenced by calibration; however, in patients with very weak or strong responses to nerve stimulation, one or more responses to TOF stimulation might be out of the recording window, and the displayed TOF response might be incorrect. In some devices, supramaximal stimulation is established concurrently with the calibration procedure.

IMPEDANCE

An alternative and novel option to ensure a constant maximum stimulus throughout the whole procedure is to control the impedance (resistance) of the skin. Indeed, as long as the resistance of the skin is below a threshold value, the neuromuscular monitoring device will stimulate with the same user-selected electrical current (i.e., 60 mA). For a maximum current of 60 mA, the maximal resistance of the skin should be equal to or lower than 5 kΩ. If the resistance of the skin is above this value, the monitor will not be able to stimulate the patient with the selected current. More recently, nerve stimulators have been introduced that indicate the level of skin impedance on the screen (e.g., TofScan by iDMed, Marseille, France). Using this approach, establishment of supramaximal stimulation is not needed to assure that nerve stimulation is effective and constantly maximal through the whole procedure.

SAFETY MARGIN

Neuromuscular transmission has a substantial margin of safety. Neuromuscular block only becomes evident when 70% to 80% of acetylcholine receptors at the neuromuscular endplate are occupied by nondepolarizing NMBDs and to produce complete block, 90% to 95% of receptors must be occupied. Thus, the currently available equipment and the currently applied stimulation patterns allow only insight to this 70% to 95% range of receptor occupancy. This should be kept in mind, especially during recovery of neuromuscular block, where 70% of the acetylcholine receptors at the neuromuscular endplate may still be occupied but no longer detectable with neuromuscular monitoring.

Types of Peripheral Nerve Stimulation

Neuromuscular function is monitored by evaluating the muscular response to supramaximal stimulation of a peripheral motor nerve. Theoretically, two types of stimulation can be used: electrical and magnetic. Electrical nerve stimulation is by far the most commonly used method in clinical practice, and it is described in detail in this chapter. In theory, magnetic nerve stimulation has several advantages over electrical nerve stimulation.[2,16] It is less painful and does not require physical contact with the body; however, the equipment required is bulky and heavy, it cannot be used for TOF stimulation, and it is difficult to achieve supramaximal stimulation with this method. As a result, magnetic nerve stimulation is not used in clinical anesthesia.

Basic Considerations

STIMULATING ELECTRODES

Electrical impulses are transmitted from stimulator to nerve by means of surface or needle electrodes. Normally, disposable pre-gelled silver or silver chloride surface electrodes are used. The conducting area should be small, approximately 7 to 11 mm in diameter (Fig.43.1). Otherwise, the current produced in the underlying nerve may not be adequate.[17] Ideally, the skin should be cleansed properly and preferably rubbed with an abrasive before application of the electrodes. When the selected current cannot be obtained with surface electrodes, needle electrodes can be used in a few exceptional cases. Although specially coated needle electrodes are commercially available, ordinary steel injection needles often suffice. A sterile technique should be used, and the needles should be placed subcutaneously to avoid direct injury to the underlying nerve.

Sites of Nerve Stimulation and Different Muscle Responses

In principle, any superficially located peripheral motor nerve can be stimulated and the response to corresponding muscle measured. Choosing the site of neuromuscular monitoring depends on several factors: the site should be easily accessible during surgery, it should allow quantitative monitoring and finally, direct muscle stimulation should be avoided. Direct muscle stimulation is characterized by weak contractions without fade persisting even at a deep level of neuromuscular blockade. The risk is increased when the stimulation electrodes are directly attached over the muscle to be assessed. To prevent direct muscle stimulation, the nerve-muscle unit should be chosen so that the site of nerve stimulation and the site of the subsequent evaluation of the twitch response are topographically (anatomically) distinct.

In clinical anesthesia, the ulnar nerve is the gold standard as a stimulation site, but the median, posterior tibial, common peroneal, and facial nerves are also sometimes used. For stimulation of the ulnar nerve, the electrodes are best applied to the volar side of the wrist (see Fig. 43.1). The distal electrode should be placed approximately 1 cm proximal to the point at which the proximal flexion crease of the wrist crosses the radial side of the tendon to the flexor carpi ulnaris muscle. The proximal electrode should preferably be placed so that the distance between the centers of the two electrodes is 3 to 6 cm (see Fig. 43.1). With this placement of the electrodes, electrical stimulation normally elicits only finger flexion and thumb adduction. If one electrode is placed over the ulnar groove at the elbow, thumb adduction is often pronounced because of stimulation of the flexor carpi ulnaris muscle. When this latter placement of electrodes (sometimes preferred in small children) is used, the active negative electrode should be at the wrist to ensure maximal response. Polarity of the electrodes is less crucial when both electrodes are close to each other at the volar side of the wrist; however, placement of the negative electrode distally normally elicits the greatest neuromuscular response.[18] When the temporal branch of the facial nerve is stimulated, the negative electrode should be placed over the nerve, and the positive electrode should be placed somewhere else over the forehead. When the posterior tibial nerve is stimulated, the electrodes should be placed close to the medial malleolus, with the same distance as described above and the negative electrode being placed distally.

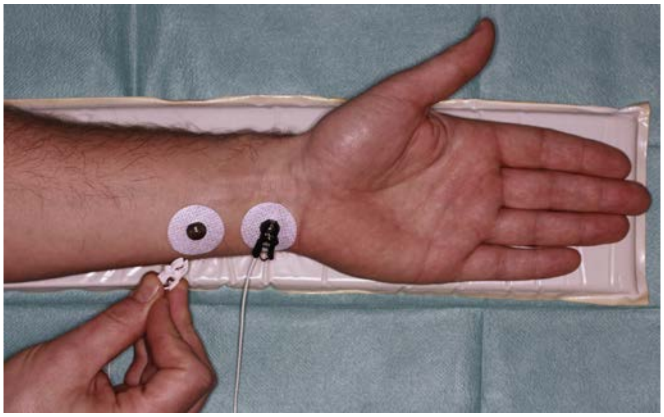

Fig. 43.1 Stimulating electrodes with the appropriate contact area in the correct position over the ulnar nerve of the left forearm.

NERVE-MUSCLE UNIT

Several nerve-muscle units may be chosen in clinical practice. Most often the ulnar nerve-adductor pollicis muscle is used.

Ulnar nerve-adductor pollicis muscle: This nerve-muscle unit is easily accessible intraoperatively if the arm is in the outstretched position and the hand in the supine position. The stimulatory response can be evaluated tactilely, visually, or by objective means. It has the lowest risk of direct muscle stimulation, because it ensures topographic separation of the stimulated nerve and the evaluated muscle by stimulating the ulnar nerve running along the median side of the arm and assessing the muscle response at the adductor pollicis muscle, which is indeed located on the lateral side of the hand.

Posterior tibial nerve-flexor hallucis brevis muscle: This nerve-muscle unit can be used for monitoring when the hands are inaccessible. The flexor hallucis brevis muscle produces flexion of the big toe following posterior tibial nerve stimulation. The characteristics (onset and recovery) of the neuromuscular block at the flexor hallucis brevis muscle is almost consistent with that of the adductor pollicis muscle.

Facial nerve-orbicularis oculi and facial nerve-corrugator supercilii muscle: When the arms are tucked under surgical drapes, quite often the only accessible site for monitoring is the head. Two facial muscles can be used as monitoring sites: the orbicularis oculi muscle and the corrugator supercilii muscle. The former encircles the orbital opening; its stimulation through the zygomatic branches of the facial nerve causes the eyelids to close. Stimulation by the temporal branch of the facial nerve of the latter one draws the medial end of the eyebrow downward, producing wrinkling of the brow. However, because the facial nerve is in direct proximity to the intrinsic mimic muscles, the risk of direct muscle stimulation is significant. Therefore, care must be

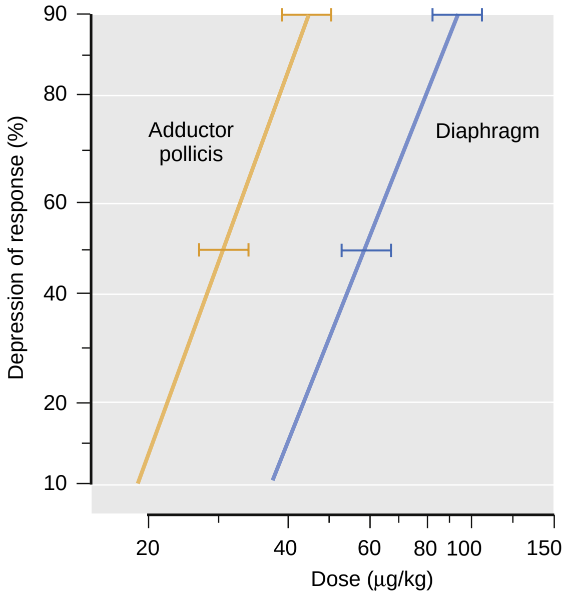

Fig. 43.2 The mean cumulative dose-response curve for pancuronium in two muscles shows that the diaphragm requires approximately twice as much pancuronium as the adductor pollicis muscle for the same amount of neuromuscular block. The depression in muscle response to the first stimulus in train-of-four nerve stimulation (probit scale) was plotted against dose (log scale). The force of contraction of the adductor pollicis was measured on a force-displacement transducer; response of the diaphragm was measured electromyographically. (From Donati F, Antzaka C, Bevan DR. Potency of pancuronium at the diaphragm and the adductor pollicis muscle in humans. *Anesthesiology*. 1986;65[1]:1–5.)

taken that the correct stimulatory response is assessed, and any other twitching muscle in the direct proximity of the stimulation electrodes is not falsely interpreted. Stimulation of the facial nerve can be accomplished with significantly lower currents: most often 25 to 30 mA are sufficient. Stimulation of these two muscles is technically difficult and the result often unsatisfactory in clinical practice.

Because different muscle groups have different sensitivities to neuromuscular blocking drugs, results obtained for one muscle cannot be automatically extrapolated to other muscles. However, most of the studies that are the base for dosing recommendations of NMBAs arise from measurement of the stimulation of the ulnar nerve. The diaphragm is among the most resistant of all muscles to both depolarizing[19] and nondepolarizing neuromuscular blocking drugs.[20] In general, the diaphragm requires 1.4- to 2.0-fold as much muscle relaxant as the adductor pollicis muscle for an identical degree of block (Fig. 43.2).[20] Also of clinical significance is that onset time is normally shorter for the diaphragm than for the adductor pollicis muscle, and the diaphragm recovers from paralysis more quickly than the peripheral muscles (Fig. 43.3).[21] The other respiratory muscles are less resistant than the diaphragm, as are the larynx and the corrugator supercilii muscles.[22-24] Most sensitive are the abdominal muscles, the orbicularis oculi muscle, the peripheral muscles of the limbs, and the geniohyoid, masseter, and upper airway muscles.[1,25-27] From a clinical point of view, the response of the corrugator supercilii to facial nerve stimulation reflects the extent of neuromuscular block of the laryngeal adductor muscles and abdominal muscles better than the response of the adductor pollicis to

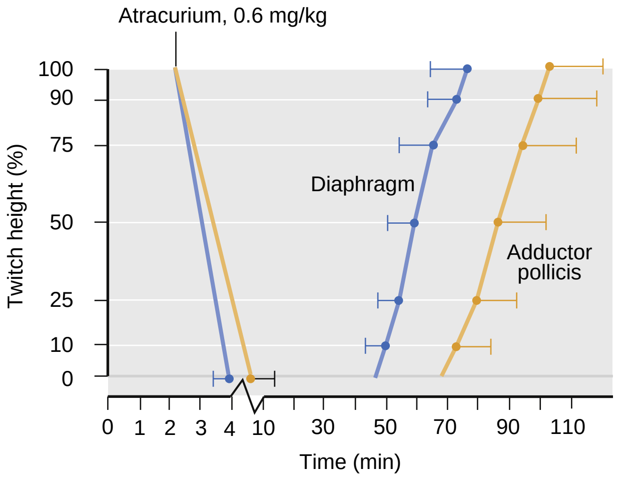

Fig. 43.3 Evolution of twitch height (mean ± SD) of the diaphragm *(blue circles)* and the adductor pollicis muscle *(yellow circles)* in 10 anesthetized patients after the administration of atracurium (0.6 mg/kg). (From Pansard J-L, Chauvin M, Lebrault C, et al. Effect of an intubating dose of succinylcholine and atracurium on the diaphragm and the adductor pollicis muscle in humans. *Anesthesiology*. 1987;67[3]:326–330.)

ulnar nerve stimulation.[24,28] Furthermore, the upper airway muscles seem to be more sensitive than the peripheral muscles.[25,26] Although some investigations using acceleromyography (AMG) have indicated small differences in the response to TOF nerve stimulation in the hand (adductor pollicis muscle) compared to the leg (flexor hallucis brevis muscle), these differences are probably of little clinical significance.[29,30] When comparing different sites of stimulation, there might be large differences between contralateral limbs (e.g., arm-to-arm variation of ± 20%).[31,32]

Although the precise source of these differences is unknown, possible explanations may be variations in acetylcholine receptor density, acetylcholine release, acetylcholinesterase activity, fiber composition, innervation ratio (number of neuromuscular junctions), blood flow, and muscle temperature.

Patterns of Nerve Stimulation

For the evaluation of the neuromuscular function, the most commonly used patterns are TOF stimulation, double-burst stimulation (DBS), and posttetanic count (PTC) stimulation. Single-twitch stimulation and tetanic stimulation are mainly used as a component in composite stimulation patterns (i.e., TOF, DBS, or PTC).

SINGLE-TWITCH STIMULATION

Background: Single-twitch stimulation is the earliest and simplest pattern. The first device specifically developed to monitor the neuromuscular block, the "St. Thomas's Hospital nerve stimulator," could only deliver a single twitch.[33] For decades it remained the only established stimulation pattern to assess neuromuscular blockade intraoperatively.

Stimulation pattern: In the single-twitch mode of stimulation, single electrical stimuli are applied to a peripheral motor nerve at frequencies ranging from 1.0 Hz (once every second) to 0.1 Hz (once every 10 seconds; Fig. 43.4) and

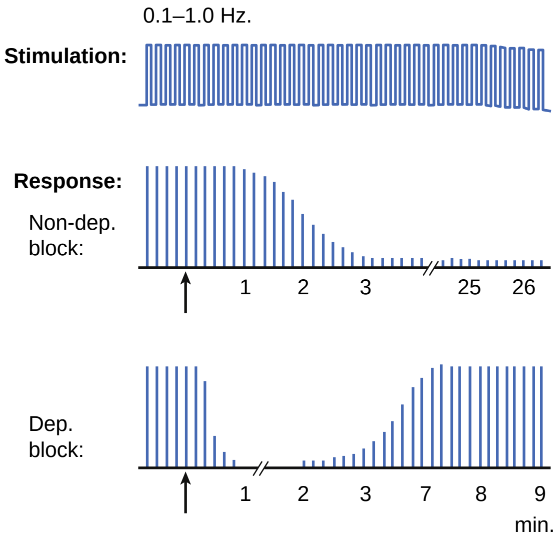

Fig. 43.4 Pattern of electrical stimulation and evoked muscle responses to single-twitch nerve stimulation (at frequencies of 0.1-1.0 Hz) after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs *(arrows)*. Note that except for the difference in time factors, no differences in the strength of the evoked responses exist between the two types of block.

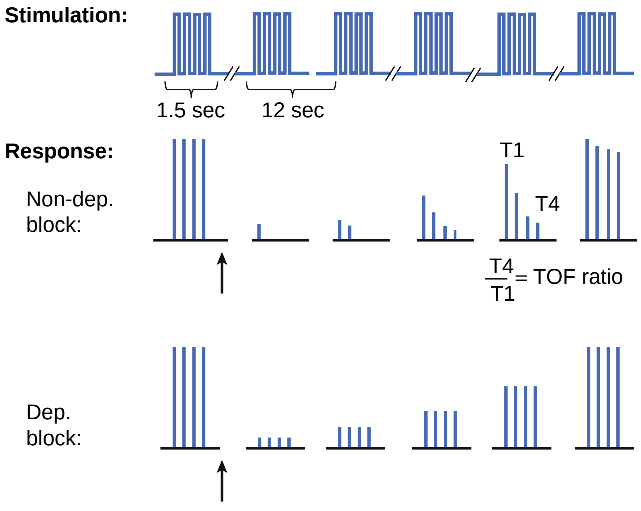

Fig. 43.5 Pattern of electrical stimulation and evoked muscle responses to train-of-four *(TOF)* nerve stimulation before and after injection of nondepolarizing (Non-dep.) and depolarizing (Dep.) neuromuscular blocking drugs *(arrows)*.

the subsequent muscle response is evaluated. The response to single-twitch stimulation depends on the frequency at which the individual stimuli are applied. If the rate of delivery is increased to greater than 0.15 Hz, the evoked response will gradually decrease and stabilize at a lower level. Therefore, results obtained with 1-Hz single-twitch stimulation cannot be compared with results obtained using, for example, 0.1-Hz single-twitch stimulation.[34] As a result, a frequency of 0.1 Hz is generally recommended.

Clinical application: To assess the degree of neuromuscular blockade after single-twitch stimulations, a comparison with a reference value recorded before administration of the NMBA is mandatory. Thus, without appropriate monitoring equipment, this stimulation pattern does not provide sufficient information of the level of block. In clinical practice, the single twitch stimulation has only limited value as a stand-alone stimulation pattern; it is mainly used as a component of the PTC stimulation and as 0.1 Hz single-twitch stimulation, it is sometimes used in scientific trials specifically to evaluate the time to onset of neuromuscular blockade. Moreover, it is the only stimulation pattern that allows, in conjunction with a monitoring device, assessing a depolarizing neuromuscular block after succinylcholine.

TRAIN-OF-FOUR STIMULATION

Background: The TOF stimulation pattern was introduced by Ali and associates[35,36] during the early 1970s. They aimed to develop a tool providing clinically reliable information throughout all phases of neuromuscular blockade with simple nerve stimulator and without the need for a monitoring device.

Stimulation pattern: TOF stimulation consists of four supramaximal stimuli given every 0.5 seconds (2 Hz; Fig. 43.5) and each stimulus in the train causes the muscle to contract. The basis for evaluation is either the number of discernible responses after TOF stimulation (i.e., TOF count) or the “fade” in the train of responses—that is, dividing the amplitude of the fourth response by the amplitude of the first response (i.e., TOF ratio). Without prior administration of a muscle relaxant, all four responses are normally the same: the TOF ratio is 1.0. During a partial nondepolarizing block, the TOF ratio decreases (fades) and is inversely proportional to the degree of block. During a partial depolarizing block, no fade occurs in the TOF response and the TOF ratio remains 1.0, independently of the level of depolarizing neuromuscular blockade. Fade in the TOF response after injection of succinylcholine signifies the development of a phase II block (discussed later in the section on depolarizing neuromuscular block).

When used continuously, an interval of at least 10 seconds should be allowed between each set (train) of four stimuli to avoid fade during the measurement.

Application: TOF stimulation is still the most frequently used stimulation pattern. The advantages of TOF stimulation are most apparent during a nondepolarizing neuromuscular block because the degree of block can be read directly from the TOF response even though a preoperative value is lacking. Clinically relevant information about the onset, surgical relaxation, and neuromuscular recovery can be obtained with the same stimulation pattern by using a simple peripheral nerve stimulator; the TOF count allows reliable assessment of the onset of neuromuscular block, and moderate blockade. Moreover, the TOF ratio can be taken as a measure of neuromuscular recovery from nondepolarizing blockade. TOF stimulation has some advantages over DBS and PTC stimulation; it is less painful and, unlike tetanic stimulation, does not generally influence subsequent monitoring of the degree of neuromuscular block. There are major limitations of the TOF stimulation pattern. First, the subjective assessment of the TOF ratio overestimates neuromuscular recovery, as the tactile of visual estimation of fade is accurate only if the TOF ratio is less than 0.4; in other words, at a TOF ratio between 0.4 and 0.9, fade cannot be detected either visually or tactically. Therefore, objective monitoring devices are needed to further quantify neuromuscular recovery and to reliably exclude residual

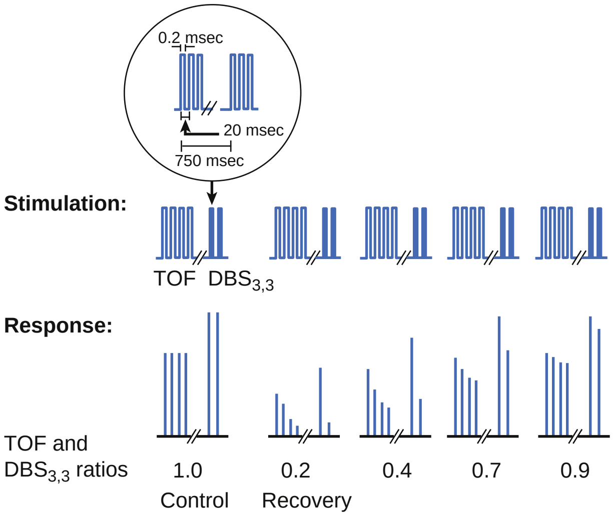

Fig. 43.6 Pattern of electrical stimulation and evoked muscle responses to train-of-four *(TOF)* nerve stimulation and double-burst nerve stimulation (i.e., three impulses in each of two tetanic bursts, *DBS$_{3,3}$*) before injection of muscle relaxants (control) and during recovery from nondepolarizing neuromuscular block. The TOF ratio is the amplitude of the fourth response to TOF divided by the amplitude of the first response. The DBS$_{3,3}$ ratio is the amplitude of the second response to DBS$_{3,3}$ divided by the amplitude of the first response. (See text for further explanation.)

paralysis. Second, the TOF stimulation does not allow the clinician to quantify intense and deep levels of neuromuscular blockade (i.e., at no responses to TOF). Finally, the TOF stimulation does not allow monitoring of the depolarizing phase I blockade.

DOUBLE-BURST STIMULATION

Background: DBS was developed by Viby-Mogensen and associates in 1989 to improve the tactile or visual evaluation of recovery from nondepolarizing neuromuscular blockade.

Stimulation pattern: DBS consists of two short bursts of 50-Hz tetanic stimulation separated by 750 ms, with a 0.2-ms duration of each square wave impulse in the burst (Fig. 43.6). The number of impulses in each burst can vary: in the DBS$_{3,3}$ mode, there are three impulses in each of the two bursts, whereas in the DBS$_{3,2}$ mode, the first burst had three impulses and the second burst consisted of only two impulses.[37-39] The individual twitches elicited by each burst blend together and are felt as one single muscle contraction. Thus, the response to DBS is two short muscle contractions and fade in the second burst compared to the first one is the basis for evaluation. In nonparalyzed muscle, both muscle contractions are of equal strength. In a partially paralyzed muscle, the second response is weaker than the first and corresponds to the typical TOF fade (see Fig 43.6). When measured mechanically, the TOF ratio correlates closely with the DBS$_{3,3}$ ratio. Compared to DBS$_{3,3,}$ tactile detection of fade is slightly improved with the DBS$_{3,2}$ mode, especially at higher TOF ratios.

Clinical application: DBS was developed with the specific aim of improving manual (tactile or visual) detection of residual nondepolarizing block under clinical conditions,[38] or during recovery and immediately after surgery. Indeed, tactile evaluation of the response to DBS is more accurate in detecting fade compared to TOF. However, a DBS is still insufficient to exclude reliably residual paralysis corresponding to a TOF ratio between 0.6 and 0.9.[39-41] Accordingly, DBS cannot replace objective monitoring.

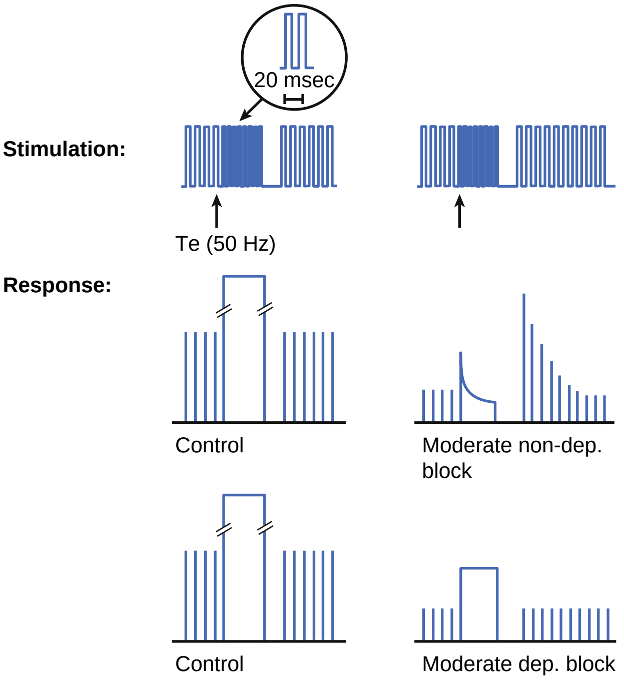

Fig. 43.7 Pattern of stimulation and evoked muscle responses to tetanic (50 Hz) nerve stimulation for 5 seconds *(Te)* and posttetanic twitch stimulation (1.0 Hz; *arrows*). Stimulation was applied before the injection of neuromuscular blocking drugs and during moderate nondepolarizing (non-dep.) and depolarizing (dep.) blocks. Note the fade in the response to tetanic stimulation, plus the posttetanic facilitation of transmission during nondepolarizing block. During depolarizing block, the tetanic response is well sustained, and no posttetanic facilitation of transmission occurs.

TETANIC STIMULATION

Background: Tetanic stimulation was proposed by Tassonyi in 1975[42] as an alternative method to evaluate residual neuromuscular blockade.

Stimulation pattern: Tetanic stimulation consists of high-frequency delivery of electrical stimuli (e.g., 50-100 Hz). The most commonly used pattern in clinical practice is 50-Hz stimulation given for 5 seconds, although some investigators have advocated the use of 100-Hz, or even 200-Hz stimulation for 1 second. In normal neuromuscular transmission, the observer detects one strong, sustained muscle contraction, and fade after tetanic stimulation is the basis for evaluation of nondepolarizing block. During a depolarizing block, the muscle response to 50-Hz tetanic stimulation for 5 seconds is sustained. In contrast, during a phase II block after the injection of succinylcholine, the response following tetanic stimulation is not sustained (i.e., fade occurs; Fig. 43.7).

Fade in response to tetanic stimulation is normally considered a presynaptic event. The traditional explanation is that at the start of tetanic stimulation, large amounts of acetylcholine are released from immediately available stores in the presynaptic nerve terminal. As these stores become depleted, the rate of acetylcholine release decreases until equilibrium between mobilization and synthesis of acetylcholine is achieved. Despite this equilibrium, the muscle response to tetanic nerve stimulation is maintained (given normal neuromuscular transmission) because the acetylcholine released is many times greater than the amount necessary to evoke a response. However, when the "margin of safety"[43] at the postsynaptic membrane (i.e., the number of free cholinergic receptors) is reduced by nondepolarizing neuromuscular blocking drugs, a typical reduction in twitch height is seen with a fade, especially during repetitive stimulation. In addition to this postsynaptic block, nondepolarizing neuromuscular blocking drugs can also block presynaptic neuronal subtype acetylcholine receptors, thereby leading to impaired mobilization of acetylcholine within the nerve terminal.[44] This effect substantially contributes to fade in the response to tetanic (and TOF) stimulation. Although the degree of fade depends primarily on the degree of neuromuscular block, fade also depends on the frequency (Hz), the length (seconds) of stimulation, and on how often tetanic stimuli are applied. Unless these variables are kept constant, results from different studies using tetanic stimulation cannot be compared.

Clinical application: Traditionally, tetanic stimulation was proposed to evaluate residual neuromuscular block. While the sensitivity of tetanic stimulation to detect residual paralysis is about 70%, its specificity is only about 50%. Especially when anesthesia was maintained with volatile anesthetics, a marked fade can be observed despite adequate neuromuscular recovery or even without prior administration of a nondepolarizing NMBA. Hence, this test is of limited value for assessing neuromuscular recovery. Furthermore, tetanic stimulation is very painful, which limits its use in unanesthetized patients. In the late phase of neuromuscular recovery, tetanic stimulation can produce lasting antagonism of neuromuscular block in the stimulated muscle such that the response of the tested site may no longer be representative of other muscle groups.[45] For all these reasons, tetanic stimulation has little, if any, use in everyday clinical anesthesia, except as a component in DBS and PTC stimulation.

POSTTETANIC COUNT STIMULATION

Background: PTC stimulation was developed by Viby-Mogensen to allow tactile or visual evaluation of profound nondepolarizing neuromuscular blockade that does not respond to TOF stimulation.[46]

Stimulation pattern: PTC is a composite stimulation pattern composed by a tetanic stimulation (50 Hz for 5 seconds) followed by 10 to 15 single twitches (i.e., PTC twitches) given at 1 Hz starting 3 seconds after the end of tetanic stimulation.[46] It is based on a phenomenon called "posttetanic potentiation": tetanic stimulation leads to a transient, exaggerated release of acetylcholine that briefly shifts the ratio of acetylcholine and NMBA at the motor endplate in favor of acetylcholine. Even if no twitch response has been discernible prior to the tetanic stimulation, noticeable muscle contractions might occur briefly after tetanic stimulation (see Fig. 43.7). The basis for evaluation of the PTC is the count of these discernible posttetanic twitches.

The response to PTC stimulation depends primarily on the degree of neuromuscular block. It also depends on the frequency and duration of tetanic stimulation, the length of time between the end of tetanic stimulation and the first posttetanic stimulus, the frequency of the single-twitch stimulation, and probably the duration of single-twitch stimulation before tetanic stimulation. When the PTC method is used, these variables should be kept constant. Because of interference between PTC stimulation and the actual neuromuscular block within the monitored hand, tetanic stimulation should ideally not be performed more often than every 6 minutes.[46]

Clinical application and limitation: Moderate levels of neuromuscular blockade (i.e., TOF count between 1 and 4) are not sufficient to reliably prevent reactions of the diaphragm and/or laryngeal muscles after stimulation. Both muscles are rather resistant to the effect of nondepolarizing NMBA. Therefore, more profound levels of neuromuscular blockade are needed in clinical situations where any bucking or coughing in response to tracheal stimulation or sudden diaphragmatic movements during surgery should be avoided. Only PTC stimulation allows assessment of these degrees of neuromuscular blockade. During intense block, there is no response to either tetanic or posttetanic stimulation (Fig. 43.8). As the period of intense neuromuscular block dissipates, the first response to posttetanic twitch stimulation occurs and is followed by a gradual return of posttetanic twitches until the first response to TOF stimulation reappears. The PTC should be 3 or less if a deep block is required for clinical reasons; at 6 to 10 PTC, the return of the first TOF response is most often imminent (Fig. 43.9).[46-50] Because tetanic stimulation should not be performed more often than every 6 minutes, this stimulation pattern cannot be applied continuously.

Equipment

Although many nerve stimulators are commercially available, not all meet the basic requirements for clinical use. The stimulus should produce a monophasic and rectangular waveform, and the length of the pulse should not exceed 0.2 to 0.3 ms. A pulse exceeding 0.5 ms may stimulate the muscle directly or cause repetitive firing. Stimulation at a constant current is preferable to stimulation at a constant voltage because current is the determinant of nerve stimulation. Furthermore, for safety reasons, the nerve stimulator should be operated by a rechargeable battery, include a battery check, and be able to generate 60 to 70 mA, but not more than 80 mA. Some commercially available stimulators can deliver just 25 to 50 mA and provide a constant current only when skin resistance ranges from 0 to 2.5 kΩ. This is a limitation, as skin resistance can increase to approximately 5 kΩ, especially during lower skin temperature. The high skin resistance can cause the current delivered to the nerve to decrease below the supramaximal level and lead to a decrease in the response to stimulation. Ideally, the nerve stimulator should have a built-in warning system, or a current level display that alerts the user when the selected current is not delivered to the nerve. Alternatively, the impedance should be indicated at the screen. The polarity of the electrodes should be indicated, and the

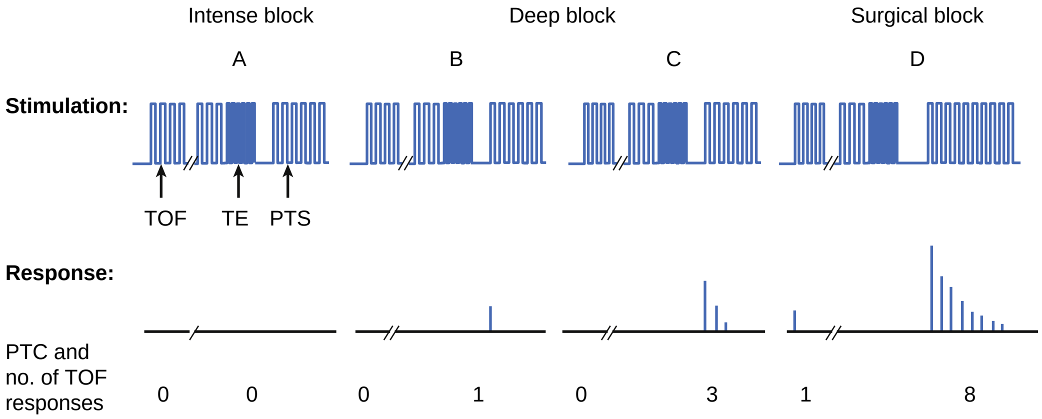

Fig. 43.8 Pattern of electrical stimulation and evoked muscle responses to train-of-four *(TOF)* nerve stimulation, 50-Hz tetanic nerve stimulation for 5 seconds *(TE)*, and 1.0-Hz posttetanic twitch stimulation *(PTS)* during four different levels of nondepolarizing neuromuscular block. During intense block of peripheral muscles (A), no response to any of the forms of stimulation occurs. During less pronounced block (deep block, B and C), there is still no response to TOF stimulation, but posttetanic facilitation of transmission is present. During surgical block (D), the first response to TOF appears and posttetanic facilitation increases further. The posttetanic count (see text) is 1 during very deep block (B), 3 during less deep block (C), and 8 during surgical (or moderate) block (D).

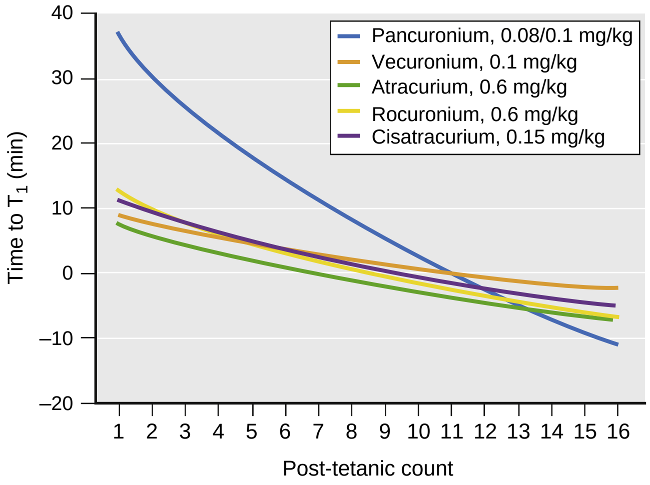

Fig. 43.9 Relationship between the posttetanic count and time when onset of train-of-four (T_1) is likely to be elicited for various neuromuscular blocking agents. (From El-Orbany MI, Joseph JN, Salem MR. The relationship of post-tetanic count and train-of-four responses during recovery from intense cisatracurium-induced neuromuscular block. *Anesth Analg.* 2003;97[1]:80–84.)

apparatus should be capable of delivering the following modes of stimulation: TOF (as both a single train and in a repetitive mode, with TOF stimulation being given every 10-20 seconds), and PTC. Some recent nerve stimulators switch automatically between TOF and PTC, depending on the level of neuromuscular blockade. If the nerve stimulator does not allow objective measurement of the response to TOF stimulation, at least one DBS mode should be available, preferably DBS$_{3,2}$.

Peripheral Nerve Stimulator

Peripheral nerve stimulators only allow stimulation of the target nerve; the subsequent muscular response is assessed subjectively either tactilely or visually. When applying TOF stimulation and evaluating the TOF count, the peripheral nerve stimulator may deliver clinically useful information about the onset of neuromuscular block or the need for an additional dose of relaxant. Moreover, the clinician could be guided for the timing and dosing of reversal agents. It is in the determination of full neuromuscular recovery these devices have clinical limitations. It is impossible to reliably exclude residual paralysis. A simple nerve stimulator acts only as a guide and should not be used as a diagnostic tool to exclude residual paralysis.

Objective Monitors

Objective monitors measure the evoked responses objectively and display it on a screen.

Several methods may be used for objective clinical monitoring of neuromuscular function: evoked mechanical response of the muscle (mechanomyography [MMG]), evoked electrical response of the muscle (electromyography [EMG]), acceleration of the muscle response (AMG), evoked electrical response in a piezoelectric film sensor attached to the muscle (kinemyography [KMG]), measurement of pressure changes in blood pressure cuff after contractions of the upper arm muscles (cuff pressure modality [CPM]), measurement of pressure change of a spherical balloon after hand contraction (compressomyography [CMG]), and measurement of low-frequency sounds evoked by the muscle contraction (phonomyography [PMG]). The different methods are described below. For further information on recording evoked responses, the reader is referred to guidelines for good clinical research practice in pharmacodynamic studies of neuromuscular blocking drugs.[17] The only objective monitors currently available are based on AMG, EMG, CPM, and KMG. The use of computer-guided administration of neuromuscular blocking drugs and "closed loop control" systems has been suggested, but no systems are commercially available.[51,52]

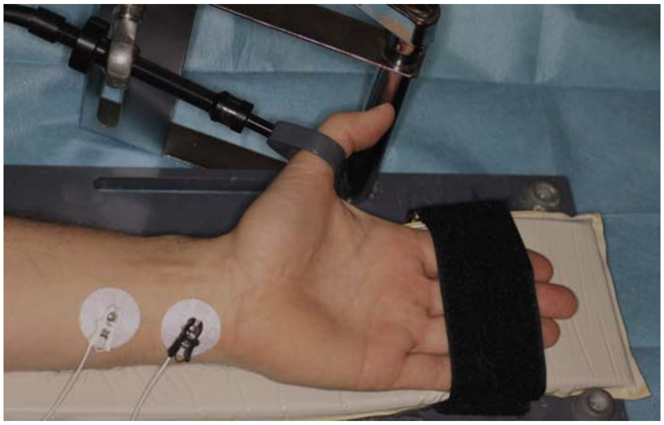

Fig. 43.10 The setup for mechanomyography. The response to nerve stimulation is measured using a force transducer (TD-100; Biometer, Odense, Denmark) placed at the proximal phalanx of the thumb.

MECHANOMYOGRAPHY

MMG measures the isometric contraction of a muscle after stimulation of the corresponding nerve. A transducer converts the force of an isometric contraction into an electrical signal. For correct and reproducible measurement, the muscle contraction needs to be isometric. In clinical anesthesia, this condition is most easily achieved by measuring the force of contraction of the thumb after the application of a resting tension of 200 to 300 g (a preload) to the thumb. When the ulnar nerve is stimulated, the thumb (the adductor pollicis muscle) acts on a force-displacement transducer (Fig. 43.10). The force of contraction is then converted into an electrical signal, which is amplified, displayed, and recorded. The arm and hand should be rigidly fixed, and care should be taken to prevent overloading of the transducer. In addition, the transducer should be placed in correct relation to the thumb (i.e., the thumb should always apply tension along the length of the transducer). It is important to remember that the response to nerve stimulation depends on the frequency with which the individual stimuli are applied and that the time used to achieve a stable control response may influence subsequent determination of the onset time and duration of block.[17] Generally, the reaction to supramaximal stimulation increases during the first 8 to 12 minutes after commencement of the stimulation (staircase phenomenon). Therefore, in clinical studies, recording of the control response (before injection of muscle relaxant) should not be made until the response has stabilized for 8 to 12 minutes or a 2- or 5-second 50-Hz tetanic stimulation has been given.[53] Even then, twitch response often recovers to 110% to 150% of the control response after paralysis with succinylcholine. This increase in response, possibly caused by a change in the contractile response of the muscle, normally disappears within 15 to 25 minutes.

Although there are numerous methods for mechanical recording of evoked mechanical responses, not all meet the criteria outlined. MMG is recognized as the gold standard of neuromuscular monitoring.[17]

Despite this status, there is no commercially available neuromuscular monitor for daily clinical use based on this principle. This type of monitor is relegated to research purpose only.

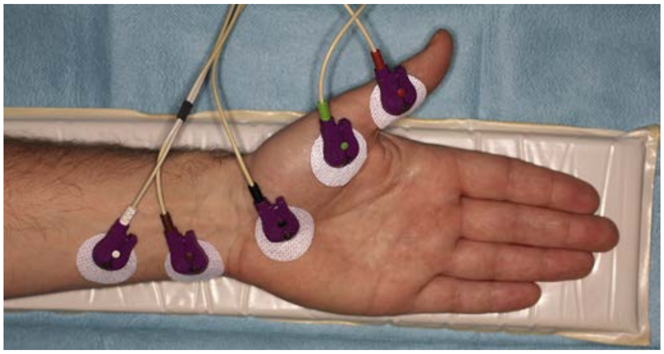

Fig. 43.11 The setup for electromyography (NMT ElectroSensor, Datex-Ohmeda, Helsinki, Finland) for recording the compound action potential from the adductor pollicis muscle.

ELECTROMYOGRAPHY

EMG is the oldest technique used for quantification of neuromuscular blockade. Evoked EMG records the compound muscle action potentials produced by stimulation of a peripheral nerve. The compound action potential is an electrical activity that for many years could be detected only by means of a preamplifier and a storage oscilloscope. Modern neuromuscular transmission analyzers are able to make online electronic analyses and graphic presentations of the EMG response.

The evoked EMG response is most often obtained from muscles innervated by the ulnar or the median nerves. Stimulating electrodes are applied as in force measurements. Most often, the evoked EMG response is obtained from the thenar or hypothenar eminence of the hand or from the first dorsal interosseous muscle of the hand, preferably with the active electrode over the motor point of the muscle (Fig. 43.11). The signal picked up by the analyzer is processed by an amplifier, a rectifier, and an electronic integrator. The results are displayed either as a percentage of control or as a TOF ratio.

Two new sites for recording the EMG response have been introduced: the larynx and the diaphragm.[54,55] Using a noninvasive disposable laryngeal electrode attached to the tracheal tube and placed between the vocal cords, it is possible to monitor the onset of neuromuscular block in the laryngeal muscles. However, the method is mainly of interest in clinical research when investigating onset times of the laryngeal muscles. In paravertebral surface diaphragmatic EMG, the recording electrodes are placed on the right of vertebrae T12/L1 or L1/L2 for monitoring the response of the right diaphragmatic crux to transcutaneous stimulation of the right phrenic nerve at the neck.[54-57] As is the case with surface laryngeal EMG, surface diaphragmatic EMG is mainly of interest in clinical research.

Evoked electrical and mechanical responses represent different physiologic events. Evoked EMG records changes in the electrical activity of one or more muscles, whereas evoked MMG records changes associated with excitation-contraction coupling and contraction of the muscle as well. For these reasons, the results obtained with these methods may differ.[57,58] Although evoked EMG responses generally correlate well with evoked mechanical responses,[38] marked differences can occur, especially in the response to succinylcholine and in the TOF ratio during recovery from a nondepolarizing block.[38,57,59]

In theory, recording of evoked EMG responses has several advantages over recording of evoked mechanical responses. Equipment for measuring-evoked EMG responses is easier to set up, the response reflects only factors influencing neuromuscular transmission, and the response can be obtained from muscles not accessible to mechanical recording. However, evoked EMG does entail some difficulties. Although high-quality recordings are possible in most patients, the results are not always reliable. For one thing, improper placement of electrodes can result in inadequate pickup of the compound EMG signal. If the neuromuscular transmission analyzer does not allow observation of the actual waveform of the compound EMG, determining optimal placement of the electrodes is difficult. Another source of unreliable results may be that fixation of the hand with a preload on the thumb might be more important than is generally appreciated, inasmuch as changes in the position of the electrodes in relation to the muscle can affect the EMG response. In addition, direct muscle stimulation sometimes occurs. If muscles close to the stimulating electrodes are stimulated directly, the recording electrodes can pick up an electrical signal even though neuromuscular transmission is completely blocked. Another difficulty is that the EMG response often does not return to the control value. Whether this situation is the result of technical problems, inadequate fixation of the hand, or changes in temperature is unknown (Fig. 43.12). Finally, the evoked EMG response is highly sensitive to electrical interference, such as that caused by diathermy.

Currently, to our knowledge, there are only a few EMG-based monitors available for clinical use, but more devices are under development.

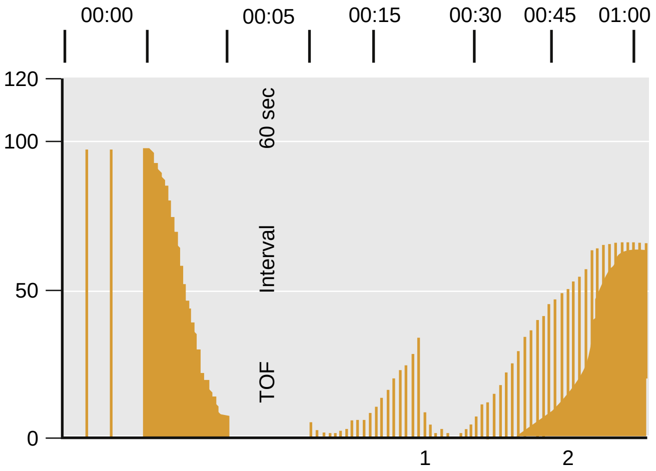

Fig. 43.12 Evoked electromyographic printout from a Relaxograph (Datex-Ohmeda, Helsinki, Finland). Initially, single-twitch stimulation was given at 0.1 Hz, and vecuronium (70 μg/kg) was administered intravenously for tracheal intubation. After approximately 5 minutes, the mode of stimulation was changed to train-of-four *(TOF)* stimulation every 60 seconds. At a twitch height (first twitch in the TOF response) of approximately 30% of control (marker 1), 1 mg of vecuronium was given intravenously. At marker 2, 1 mg of neostigmine was given intravenously, preceded by 2 mg of glycopyrrolate. The printout also illustrates the common problem of failure of the electromyographic response to return to the control level. (Courtesy Datex-Ohmeda, Helsinki, Finland.)

ACCELEROMYOGRAPHY

AMG was developed specifically for clinical use and is widely practiced. The technique of AMG is based on Newton's second law: force = mass × acceleration, it measures the isotonic acceleration of the stimulated muscle.[60] If mass is constant, acceleration is directly proportional to force. Accordingly, after nerve stimulation, one can measure not only the evoked force but also acceleration of the thumb.

AMG uses a piezoelectric ceramic wafer with electrodes on both sides. Exposure of the electrode to a force generates an electrical voltage proportional to acceleration of the electrode. Consequently, when an accelerometer is fixed to the thumb and the ulnar nerve is stimulated, an electrical signal is produced whenever the thumb moves (Fig. 43.13). This signal can be analyzed in a specially designed analyzer[61] or displayed on a recording system.

AMG is a simple method of analyzing neuromuscular function, both in the operating room and in the intensive care unit. Although good correlation exists between the TOF ratio measured by this method and the TOF ratio measured with a force-displacement transducer or EMG,[60,62,63] measurements made via AMG are not directly comparable with results obtained by the other two methods.[63-69] When AMG is used with a free-moving thumb, as originally suggested,[60] wide limits of agreements in twitch height (T1) and TOF ratio and differences in the onset and recovery course of block between AMG and MMG have been found. Moreover, the AMG control TOF ratio is consistently higher than when measured with a force-displacement transducer. In accordance with this, several studies have indicated that when using AMG, the TOF ratio indicative of sufficient postoperative neuromuscular recovery is 1.0 rather than 0.90, as when measured by MMG or EMG in the adductor pollicis muscle.[6,68,70-72] In contrast to MMG and EMG, the control baseline TOF value before administration of a neuromuscular blocking drug is most often 1.1 to 1.2 when measured with AMG, and in some patients is as high as 1.4. A high control baseline value probably indicates that the TOF ratio necessary for excluding residual curarization is equally higher. For instance, in a patient with a high control baseline value (e.g., TOF = 1.2), it is to be expected that a higher TOF ratio during recovery is necessary to exclude residual

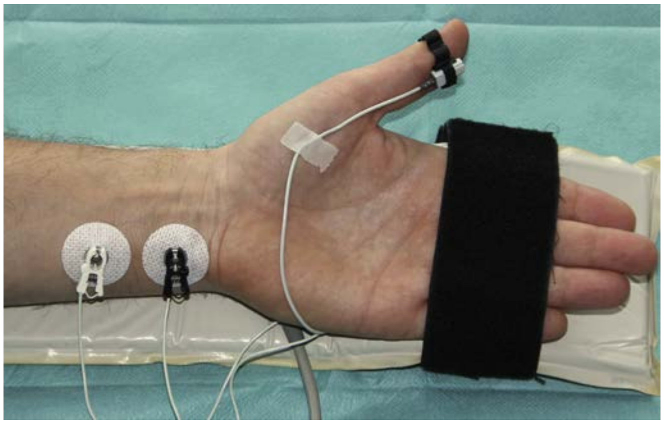

Fig. 43.13 The setup of acceleromyography without preload (TOF Watch, Biometer, Odense, Denmark). The response to nerve stimulation is measured with a small piezoelectric acceleration transducer placed distally on the volar site of the thumb.

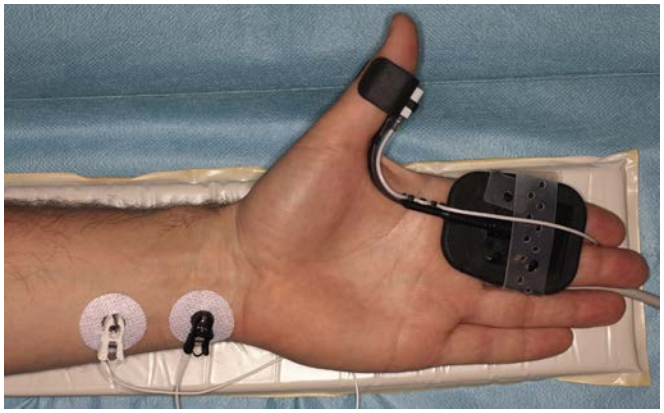

Fig. 43.14 The setup of acceleromyography with preload (TOF Watch with Hand Adapter, Biometer, Odense, Denmark). The piezoelectric acceleration transducer is placed in the Hand Adapter. The stretching wing ensures that the thumb does not touch the palm of the hand.

block compared with a patient with a low control baseline value (e.g., TOF = 0.95). It is generally accepted that the TOF ratio should be at least 0.90 to exclude clinically significant residual paralysis; using the preceding example, a TOF ratio of 1.08 (90% of 1.2) would represent safe recovery in the first patient, whereas a TOF ratio of 0.86 (90% of 0.95) would suffice in the other patient. To overcome such problems, it has been suggested to refer the actually obtained TOF ratios during recovery to the baseline control TOF ratio (normalization).[67,72-76] Currently, no commercially available monitors can "normalize" the TOF ratio automatically. Intuitively, for excluding residual block using AMG, a TOF ratio of at least 1.0 should be targeted to exclude residual block.[67,68,72,74]

One reason for the wide limits of agreement between AMG and MMG is probably and paradoxically connected with one of the originally claimed advantages of the method, that fixation of the hand could be reduced to a minimum as long as the thumb could move freely.[60] In clinical practice, it is often not possible to ensure that the thumb can move freely and that the position of the hand does not change during the surgical procedure. The evoked response can therefore vary considerably. Several solutions have been proposed, but the use of an elastic preload on the thumb improves the precision without compromising the agreement between results obtained with AMG and MMG (Fig. 43.14).[67,68] Several studies have indicated that objective monitoring with AMG reduces and almost eliminates the problem of postoperative residual neuromuscular block.[67,77-81]

When the thumb is not available for monitoring during surgery, some clinicians prefer to monitor the AMG response of the orbicularis oculi or the corrugator supercilii in response to facial nerve stimulation.[28] However, neuromuscular monitoring of both sites with AMG is subject to both large uncertainty regarding the extent of paralysis and high risk of direct muscle stimulation, and it cannot be recommended for routine monitoring. It provides only a rough estimate of the degree of block of the peripheral muscles.[82,83]

AMG was one of the first widely distributed commercially available monitors and has therefore become the standard for qualitative monitoring in the clinical setting. Today, AMG devices are available as portable monitors as well as integrated in the anesthesia monitor.

Recently, AMG monitors with three-dimensional piezoelectric transducers were introduced, which sense the motion of the thumb in all directions,[83a,83b] and not just in one plane. This might further improve the reliability of the AMG technology. This novel method has been compared to the TOF-Watch (one-dimensional AMG) in two small studies. Although both studies showed some disagreement between the two methods, the authors agreed that the three-dimensional monitor may be used in clinical practice. An advantage seems to be that the monitors' integrated internal check-up ensuring that all components including the piezoelectric element are functional is developed. The newest monitors also display the impedance and calculate automatically a modified normalized TOF ratio. Hopefully, the new generation of AMG monitors becomes even more user-friendly and more reliable.

KINEMYOGRAPHY

The technique of KMG is based on the principle that stretching or bending a flexible piezoelectric film (e.g., one attached to the thumb) in response to nerve stimulation generates a voltage that is proportional to the amount of stretching or bending.[84,85]

Few studies have evaluated the function of these monitors.[84-86] Limited data indicate not only a good relationship between results obtained with KMG, AMG, and MMG, but also wide limits of agreement between the methods. Therefore, although KMG may be a valuable clinical tool, the values obtained in an individual patient with this method can vary from those obtained with MMG or AMG. Only one device based on this principle is available commercially in two sizes (adult and pediatric): the NMT MechanoSensor (Datex-Ohmeda, Helsinki, Finland).

CUFF PRESSURE MODALITY (CPM)

The cuff modality detects changes in cuff pressure due to muscle contraction. Electrodes integrated into a blood pressure cuff stimulate the brachial plexus at the humeral level. The subsequent bulk contraction of the upper arm generates pressure change in the blood pressure cuff which is analyzed and displayed at the monitor. However, only limited data are currently available and further clinical investigations are needed to prove the reliability and reproducibility of the new monitoring modality. One monitor based on this technology is commercially available: the TOF-Cuff NMT monitor (RGB Medical devices, Madrid, Spain).

COMPRESSOMYOGRAPHY

CMG measures pressure changes in a hand-held balloon. Following ulnar nerve stimulation, the force of muscle contraction of the hand muscles is transmitted to a balloon secured in the patient's hand. Despite encouraging results of the only publication investigating the device,[49] this technique has not been further developed and is not commercially available.

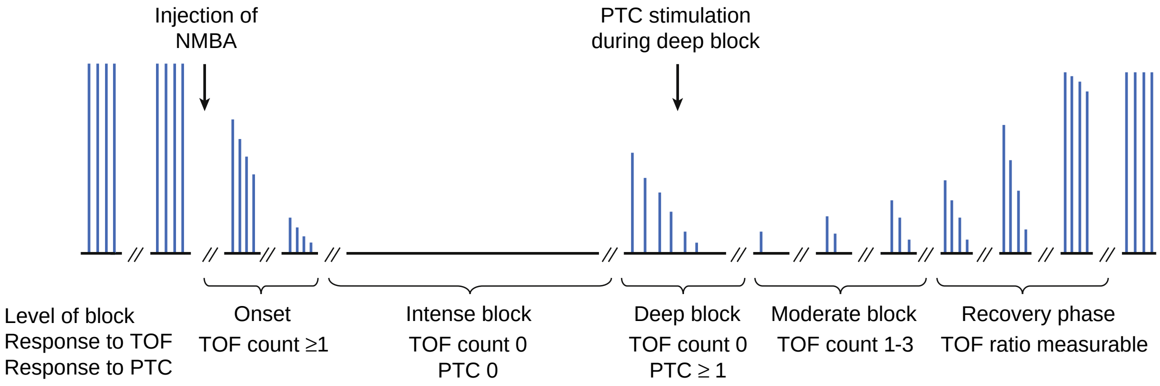

Fig. 43.15 Levels of block after a normal intubating dose of a nondepolarizing neuromuscular blocking agent *(NMBA)* as classified by posttetanic count *(PTC)* and train-of-four *(TOF)* stimulation. During intense (profound) block, there are no responses to either TOF or PTC stimulation. During deep block, there is response to PTC but not to TOF stimulation. Intense (profound) block and deep block together constitute the "period of no response to TOF stimulation." Reappearance of the response to TOF stimulation heralds the start of moderate block. Finally, when all four responses to TOF stimulation are present and a TOF ratio can be measured, the recovery period has started. (From Fuchs-Buder T, Claudius C, Skovgaard LT, et al. Good clinical research practice in pharmacodynamic studies of neuromuscular blocking agents II: The Stockholm revision. *Acta Anaesthesiol Scand*. 2007;51[7]:789–808.)

PHONOMYOGRAPHY

PMG measures the intrinsic low-frequency sounds of muscle contraction with special microphones following nerve stimulation. PMG has been evaluated for clinical and research purposes by one study group. This group reports good correlation between evoked acoustic responses and those obtained with more traditional methods of recording, such as MMG, EMG, and AMG.[31,87-92] A potential advantage of PMG, however, is that the method can be applied not only to the adductor pollicis muscle, but also to other muscles of clinical interest such as the diaphragm, larynx, and eye muscles. In addition, the ease of application is attractive. However, PMG-based monitors are not currently commercially available.

Evaluation of Recorded Evoked Responses

In daily clinical practice, the recorded response to TOF stimulation and PTC stimulation are typically used to explain how to evaluate the degree of neuromuscular block during clinical anesthesia.

NONDEPOLARIZING NEUROMUSCULAR BLOCK

After injection of a nondepolarizing neuromuscular blocking drug in a dose sufficient for smooth tracheal intubation, TOF recording demonstrates four phases, or levels, of neuromuscular block: intense block, deep block, moderate or surgical block, and recovery (Fig. 43.15).

Intense Neuromuscular Block

Intense or profound neuromuscular block occurs within 3 to 6 minutes of injection of an intubating dose of a nondepolarizing muscle relaxant, depending on the drug and the dose given. This phase is also called the "period of no response" because no response to any pattern of nerve stimulation occurs. The length of this period varies, again depending primarily on the duration of action of the muscle relaxant and the dose given. The sensitivity of the patient to the drug also affects the period of no response. An intense block cannot be antagonized with a cholinesterase inhibitor (e.g., neostigmine), and only a high dose of sugammadex (16 mg/kg) can antagonize an intense block caused by rocuronium or vecuronium.[93,94]

Deep Neuromuscular Block

Intense neuromuscular block is followed by a period of deep neuromuscular block, characterized by absence of response to TOF stimulation, but with the presence of at least one response to PTC stimulation (i.e., PTC ≥1; compare with Fig. 43.8). To avoid diaphragmatic movements and thus, to assure surgical stillness and improve surgical space conditions during laparoscopic abdominal procedures, deep neuromuscular blockade corresponding to ≤3 PTC responses is recommended.[49] Although prediction of the duration of a deep neuromuscular block is difficult, correlation usually exists between PTC stimulation and the time until reappearance of the first response to TOF stimulation (see Fig. 43.9). Attempts to reverse a deep neuromuscular block with neostigmine are usually impossible. However, a deep neuromuscular block caused by rocuronium or vecuronium can be antagonized completely within a few minutes using a dose of sugammadex of 4 mg/kg.[95-97]

Moderate Neuromuscular Block

Moderate neuromuscular block begins when the first response to TOF stimulation appears. This phase is characterized by a gradual return of the four responses to TOF stimulation. Furthermore, good correlation exists between the degree of neuromuscular block and the number of responses to TOF stimulation. When only one response is detectable, the degree of neuromuscular block (the depression in twitch tension) is 90% to 95%. When the fourth response reappears, neuromuscular block is usually 60% to 85%.[98,99] The presence of one or two responses in the TOF pattern normally indicates sufficient relaxation for most surgical procedures. During light anesthesia, however, patients may move, buck, or cough; therefore, a deeper block (or a deeper level of anesthesia) may be necessary when elimination of sudden movements or facilitation of surgery is necessary.

Antagonism of neuromuscular block with neostigmine should usually not be attempted when the block is intense or deep. Even if some reversal occurs, it will often be inadequate, regardless of the dose of neostigmine administered.[100] Furthermore, after the administration of large doses of muscle relaxants, reversal of the block with neostigmine to clinically normal activity is not always possible if only one TOF response is present. In general, antagonism with neostigmine should not be initiated before all four responses after TOF stimulation are observed. Even then, sufficient recovery may take time and cannot be guaranteed unless documented using objective monitoring.[101-103]

Antagonism of moderate block induced by rocuronium and vecuronium can be achieved with a small dose of sugammadex (2 mg/kg) within a few minutes.[104-106] However, the reappearance of neuromuscular blockade has been reported by anesthesiologists from Japan[107] when the 2 mg/kg dose has been used. However, they did not monitor the degree of neuromuscular blockade; did the reappearance of neuromuscular blockade occur because of inadequate monitoring or too small a dose of sugammadex? Although the antagonism of neuromuscular block from sugammadex seems to be fast and predictable, neuromuscular monitoring is mandatory for proper dosing, and objective monitoring should still be used until the TOF ratio is 0.9 to 1.0.

Recovery from Neuromuscular Block

Return of the fourth response in the TOF heralds the recovery phase. During neuromuscular recovery, a reasonably good correlation exists between the actual TOF ratio and clinical observation, but the relationship between the TOF ratio and signs and symptoms of residual block varies greatly among patients.[81,100] When the TOF ratio is 0.4 or less, the patient is generally unable to lift the head or arm. Tidal volume may be normal, but vital capacity and inspiratory force is reduced. When the ratio is 0.6, most patients are able to lift their head for 3 seconds, open their eyes widely, and stick out their tongue, but vital capacity and inspiratory force are often still reduced. At a TOF ratio of 0.7 to 0.75, the patient can normally cough sufficiently and lift the head for at least 5 seconds, but grip strength may still be as low as about 60% of control.[108] When the ratio is 0.8 and higher, vital capacity and inspiratory force are normal.[36,109-111] The patient may, however, still have diplopia, blurred vision, and facial weakness (Table 43.1).[81,108]

TABLE 43.1 Clinical Signs and Symptoms of Residual Paralysis in Awake Volunteers after Mivacurium-Induced Neuromuscular Block

Train-of-Four Ratio	Signs and Symptoms
0.70-0.75	Diplopia and visual disturbances
	Decreased handgrip strength
	Inability to maintain apposition of the incisor teeth
	"Tongue depressor test" negative
	Inability to sit up without assistance
	Severe facial weakness
	Speaking a major effort
	Overall weakness and tiredness
0.85-0.90	Diplopia and visual disturbances
	Generalized fatigue

From Kopman AF, Yee PS, Neuman GG. Relationship of the train-of-four fade ratio to clinical signs and symptoms of residual paralysis in awake volunteers. *Anesthesiology*. 1997;86(4):765–761.

However, the TOF ratio must exceed 0.90 when recorded with MMG or EMG, and 1.0 when using AMG to exclude clinically important residual neuromuscular block.[1,3,38,67,68,70,112-116] Moderate degrees of neuromuscular block can impair carotid body chemosensitivity to hypoxia with absent ventilatory response to arterial desaturation.[3,112,114,116] Moreover, residual block (TOF < 0.90) is associated with functional impairment of the pharyngeal and upper esophageal muscles, which most probably predisposes to regurgitation and aspiration of gastric contents.[1] Eikermann and colleagues[4] have documented that partial neuromuscular block, even to a degree that does not evoke dyspnea or oxygen desaturation, can decrease inspiratory upper airway volume and can evoke partial inspiratory airway collapse.[4] Also, residual block (TOF < 0.70) caused by the long-acting muscle relaxant pancuronium is a significant risk factor for the development of postoperative pulmonary complications (Table 43.2 and Fig. 43.16).[113] Intraoperative neuromuscular monitoring, followed by appropriate pharmacological reversal, reduces the risk of residual neuromuscular block and results in fewer patients with hypoxemic events or airway obstruction in the postanesthesia care unit.[80] Even in volunteers without sedation or impaired consciousness, a TOF ratio of 0.90 or less can impair the ability to maintain the airway.[77,108,117] Even small degrees of residual block are unpleasant for patients, causing symptoms such as general weakness and blurred vision.[81] In summary, adequate recovery of neuromuscular function requires the return of an MMG or EMG TOF ratio to at least 0.90, and an AMG TOF ratio to at least 1.0 (or normalized to 0.90),[74] which cannot be guaranteed without objective neuromuscular monitoring.[78,79,81,118-121]

DEPOLARIZING NEUROMUSCULAR BLOCK (PHASE I AND II BLOCKS)

Fade and posttetanic facilitation are the basis for evaluation of all stimulation patterns applied in clinical practice (i.e., TOF, DBS, and PTC stimulation). It is important to realize that during depolarizing neuromuscular phase I block, neither fade nor posttetanic facilitation occurred. Thus, the usually applied stimulation patterns do not allow assessment of depolarizing neuromuscular block. After TOF stimulation, all four responses are reduced at the same degree, no fade occurred, and all four disappear simultaneously. Thus, independently of the degree of depolarizing neuromuscular block, the TOF-ratio remains 1 and the TOF-count is either 4 or 0.

Patients with normal plasma cholinesterase activity who are given a moderate dose of succinylcholine (0.5-1.5 mg/kg) undergo a typical depolarizing neuromuscular block (phase I block; i.e., the response to TOF or tetanic stimulation does not fade, and no posttetanic facilitation of

TOF < 0.70	59	10	16.9*	24	1	4.2

*$P < .02$ versus patients in the same group with a train-of-four ratio of 0.70 or greater.

Results from a prospective, randomized, and blinded study of postoperative pulmonary complications (POPC) in a total of 691 adult patients undergoing abdominal, gynecologic, or orthopedic surgery and receiving either pancuronium, atracurium, or vecuronium.[82] In 4 of the 46 patients with POPC (1 in the pancuronium group and 3 in the atracurium and vecuronium groups), the train-of-four (TOF) ratio was not available. Because there were no significant differences in the two groups of patients given the intermediate-acting muscle relaxants, the data from these groups are pooled.

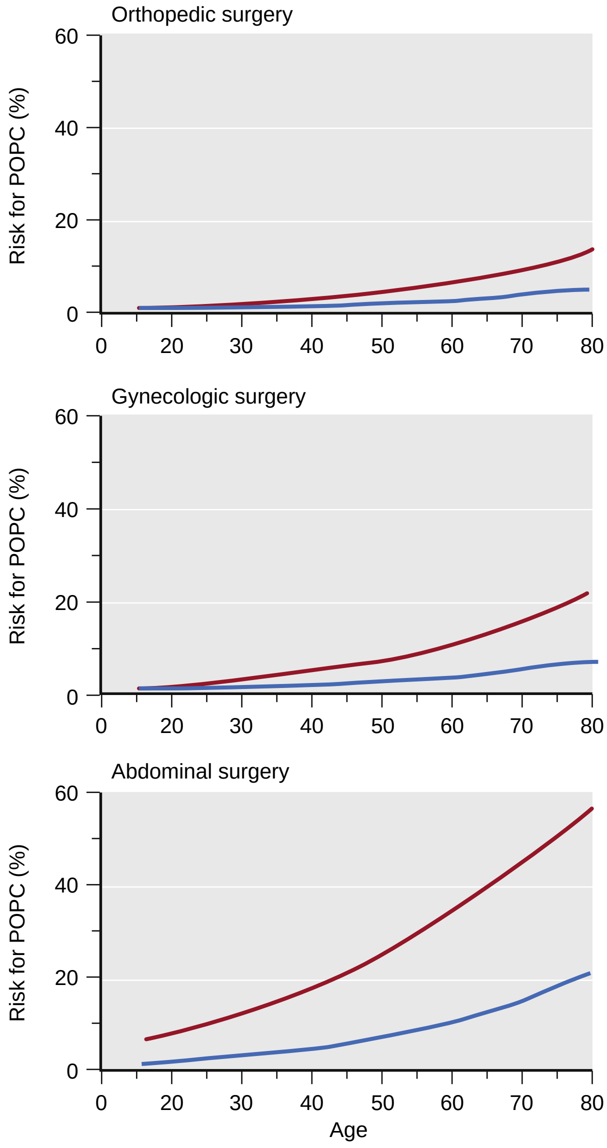

Fig. 43.16 Predicted probabilities of a postoperative pulmonary complication *(POPC)* in different age groups in orthopedic, gynecologic, and major abdominal surgery with duration of anesthesia of less than 200 minutes. The *red lines* represent patients with residual neuromuscular block (train-of-four [TOF] < 0.70) after the administration of pancuronium; the *blue lines* represent patients with a TOF of 0.70 or greater after the administration of pancuronium, as well as all patients after the administration of atracurium and vecuronium, independent of the TOF ratio at the end of anesthesia.[113]

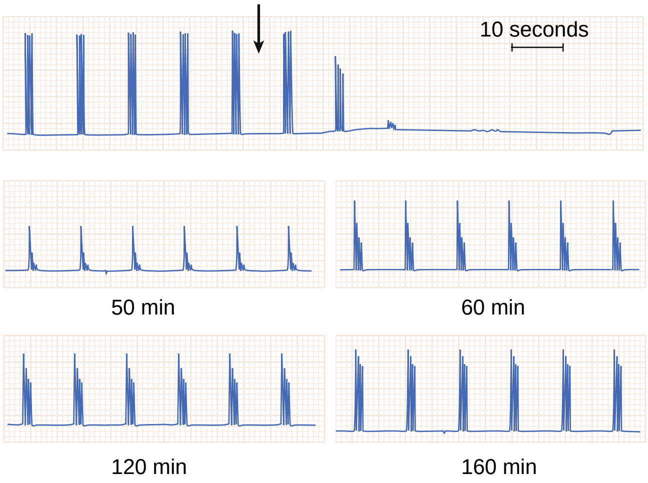

Fig. 43.17 Typical recording of the mechanical response to train-of-four ulnar nerve stimulation after injection of 1 mg/kg of succinylcholine *(arrow)* in a patient with genetically determined abnormal plasma cholinesterase activity. The prolonged duration of action and the pronounced fade in the response indicate a phase II block.

transmission occurs. All four responses are reduced at the same degree [TOF ratio is 1.0] or 0). In contrast, some patients with genetically determined abnormal plasma cholinesterase activity who are given the same dose of succinylcholine undergo a nondepolarizing-like block characterized by fade in the response to TOF and tetanic stimulation and the occurrence of posttetanic facilitation of transmission (Fig. 43.17). This type of block is called a *phase II block* (dual, mixed, or desensitizing block). In addition, phase II blocks sometimes occur in genetically normal patients after repetitive bolus doses or a prolonged infusion of succinylcholine. Therefore, in a clinical setting, TOF stimulation can be used to distinguish depolarizing phase I block and phase II block. Patients with normal plasma cholinesterase activity would recover from the neuromuscular block within a few minutes, showing four equally weak responses (TOF ratio 1.0), which quickly become stronger (still at TOF ratio 1.0). In contrast, patients with abnormal plasma cholinesterase activity and subsequent phase II block would not recover quickly and will return with a TOF count of 1, slowly increasing to 2, 3, and last 4 counts—then having a fade of TOF (TOF-ratio <1.0) during recovery as seen with nondepolarizing block.

From a therapeutic point of view, a phase II block in normal patients must be differentiated from a phase II block in patients with abnormal cholinesterase activity. In healthy patients, a phase II block can be antagonized by administering a cholinesterase inhibitor a few minutes after discontinuation of succinylcholine. In patients with abnormal genotypes, however, the effect of intravenous injection of a cholinesterase inhibitor (e.g., neostigmine) is unpredictable because it inhibits acetylcholinesterase and plasma-cholinesterase. For example, neostigmine can potentiate the block dramatically, temporarily improve neuromuscular transmission, and then potentiate the block or partially reverse the block, all depending on the time elapsed since administration of succinylcholine and the dose of neostigmine given. Therefore, unless the cholinesterase genotype is known to be normal, antagonism of a phase II block with a cholinesterase inhibitor should be undertaken with extreme caution. Even if neuromuscular function improves promptly, patient surveillance should continue for at least 1 hour.

Use of Nerve Stimulators in Daily Clinical Practice

Whenever a neuromuscular blocking drug is administered to a patient, objective monitoring of the evoked response using recording equipment is the best way to evaluate the neuromuscular block.[121a] However, tactile and visual evaluation are still common forms of clinical neuromuscular monitoring, not least when recording equipment is not available or considered unreliable. The following is a description of how to use nerve stimulators with or without recording equipment (objective monitoring).

PREPARATIONS BEFORE INDUCTION OF ANESTHESIA AND ADMINISTRATION OF THE NEUROMUSCULAR BLOCKING AGENT

First, for reliable stimulation, careful cleansing of the skin and proper placement and fixation of electrodes are essential. When the ulnar nerve is used for nerve stimulation, one should take advantage of the fact that the nerve follows the artery by placing the electrodes above the pulse. This placement gives the best response (see Fig. 43.1). Second, every effort should be taken to prevent central cooling, as well as cooling of the extremity being evaluated. Both central and local surface cooling of the adductor pollicis muscle can reduce twitch tension and the TOF ratio.[122-124] Peripheral cooling can affect nerve conduction, decrease the rate of release of acetylcholine and muscle contractility, increase skin impedance, and reduce blood flow to the muscles, thus decreasing the rate of removal of muscle relaxant from the neuromuscular junction. These factors might account for the occasional and pronounced difference in muscle response between a cold extremity and the contralateral warm extremity.[125]

USE OF A NERVE STIMULATOR DURING INDUCTION OF ANESTHESIA

The nerve stimulator should be attached to the patient before induction of anesthesia but should not be turned on until after the patient is unconscious.

Single-twitch stimulation at 1 Hz can be used initially when seeking supramaximal stimulation. However, after supramaximal stimulation has been ensured and before the muscle relaxant is injected, the recording equipment (when using objective monitoring) should be calibrated to ensure that the response is in the measurement window and the response to 1 Hz stimulation is set to 100%. Currently, all commercially available devices have an automatic calibration modus. Without calibration, the recorded response to nerve stimulation might differ significantly from the visual or tactile response throughout all levels of neuromuscular block; therefore, the mode of stimulation should be changed to TOF (or 0.1-Hz twitch stimulation). When the response to this stimulation is observed (the control response), the neuromuscular blocking drug is injected. However, devices with integrated impedance measurement do not need calibration, but at least one TOF stimulation without NMBA should be registered, allowing to normalize the recovery TOF-ratio. Although the trachea is often intubated when the response to TOF stimulation disappears, postponement of this procedure for 30 to 90 seconds, depending on the muscle relaxant used, usually produces better conditions.

When possible, the response to nerve stimulation should be evaluated at the thumb (rather than at the fifth finger). Direct stimulation of the muscle often causes subtle movement of the fifth finger when no response is present at the thumb. Finally, the different sensitivities of various muscle groups to neuromuscular blocking drugs should always be kept in mind.

USE OF A NERVE STIMULATOR DURING SURGERY

If tracheal intubation is facilitated by the administration of succinylcholine, no more muscle relaxant should be given until the response to nerve stimulation reappears or the patient shows other signs of returning neuromuscular function. If plasma cholinesterase activity is normal, the muscle response to TOF nerve stimulation reappears within 4 to 8 minutes.

When a nondepolarizing neuromuscular drug is used for tracheal intubation, a longer-lasting period of intense block usually follows. During this period of no response to TOF and single-twitch stimulation, the time until the return of response to TOF stimulation can be evaluated by PTC (see Fig. 43.9 and Fig. 43.18).

For most surgical procedures requiring muscle relaxation, it is not necessary to have a deep or intense block, provided that the patient is adequately anesthetized. If a nondepolarizing relaxant is used, a moderate level of neuromuscular block with one or two responses to TOF stimulation is sufficient. However, because the respiratory muscles (including the diaphragm) are more resistant to neuromuscular blocking drugs than the peripheral muscles are, the patient may breathe, hiccup, or even cough at this moderate level of block. Moreover, tonus of the diaphragm might impede the surgical conditions, especially during abdominal laparoscopic surgery. To ensure paralysis of the diaphragm, neuromuscular block of the peripheral muscles must be deep so that the PTC is 1-3 at the thumb.

The disadvantages of sustaining a deep or intense neuromuscular block is that at these levels of block, the muscles

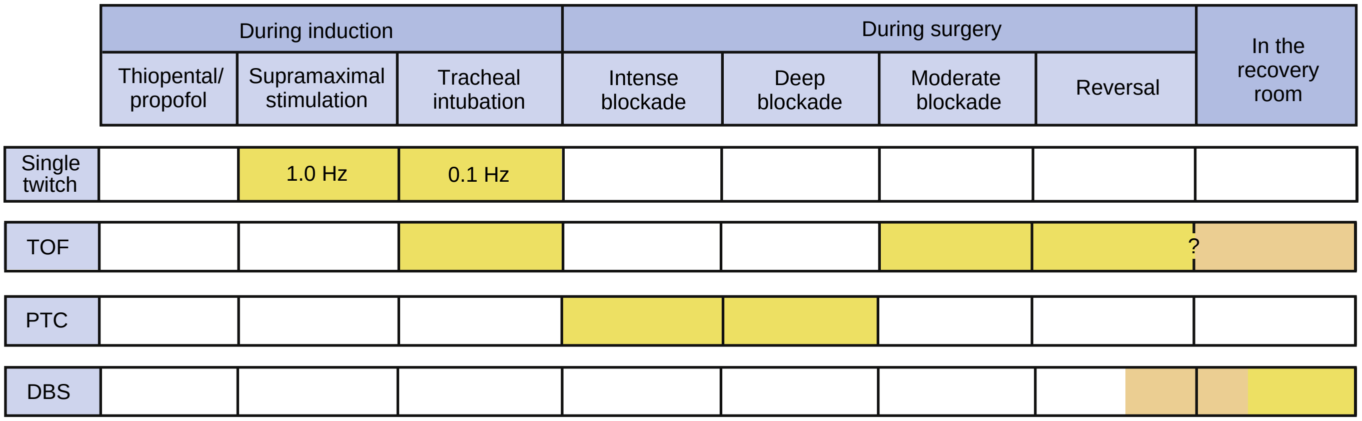

Fig. 43.18 Diagram showing when the different modes of electrical nerve stimulation can be used during clinical anesthesia. *Dark areas* indicate appropriate use and *light areas*, less effective use. Modes of nerve stimulation are train-of-four *(TOF)* stimulation; posttetanic count *(PTC)*; double-burst stimulation *(DBS)*; and the question mark (?), indicating that TOF is less useful in the recovery room unless measured with mechanomyography, electromyography, or acceleromyography. (See text for further explanation.)

are completely paralyzed and the patient cannot signal awareness with voluntary or involuntary movements. Another disadvantage is that deep or intense block cannot readily be reversed by neostigmine. Only sugammadex can reverse a deep or intense neuromuscular block (if caused by rocuronium or vecuronium).

USE OF A NERVE STIMULATOR DURING REVERSAL OF NEUROMUSCULAR BLOCK

Antagonism of nondepolarizing neuromuscular block is most often facilitated with a cholinesterase inhibitor, such as neostigmine, or with the selective relaxant binding agent sugammadex when the neuromuscular block is achieved using rocuronium or vecuronium.

Antagonism with neostigmine should not be initiated before at least all four responses to TOF stimulation are present. Reversal of neuromuscular block will not be hastened and can possibly be delayed by giving neostigmine when no response to peripheral nerve stimulation is present. Moreover, even when there are four responses to TOF stimulation, the reversal is slow and insufficient in some patients. With a large dose of neostigmine (e.g., 5 mg/70 kg), the median time to achieve a TOF ratio of 0.90 is 15 to 20 minutes, and it will take approximately 90 to 120 minutes to achieve a TOF ratio of 0.90 in 95% of the patients after an intermediate-acting neuromuscular blocking drug (e.g., rocuronium).[126] Conversely, a large dose of neostigmine after full recovery might give a paradoxical block with decreasing TOF ratio.[127-131]

When rocuronium or vecuronium is used, the selective relaxant binding drug sugammadex can be used for reversal.[104,105] Sugammadex encapsulates rocuronium and vecuronium with a high affinity, thereby antagonizing the neuromuscular blocking effect. Three different doses of sugammadex are recommended according to the level of block. A large dose (16 mg/kg) is given during intense block (no response to PTC stimulation),[93,94] a medium dose (4 mg/kg) during deep block (at least one response to PTC),[95-97] and a low dose (2 mg/kg) during moderate block (two or more responses to TOF stimulation).[104-106] In most patients, all levels of neuromuscular block are reversed within 2 to 5 minutes. However, appropriate dosing requires neuromuscular monitoring and residual neuromuscular block can be excluded only with objective monitoring (TOF ratio, 0.9-1.0), even after routine use of sugammadex.[107,132]

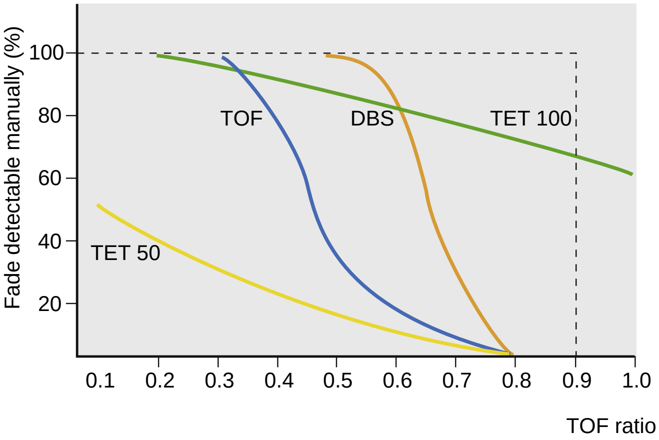

Fig. 43.19 Fade detectable by feel in the response to train-of-four *(TOF)*, double-burst stimulation *($DBS_{3,3}$)*, and 50- and 100-Hz tetanic stimulation (*TET* 50 and TET 100) in relation to the true TOF ratio, as measured mechanically. The axis indicates the percentage of instances in which fade can be detected at a given TOF ratio.[37,39,72] It appears that it is not possible to exclude residual neuromuscular block by any of the methods. (See text for further explanation.)

During recovery of neuromuscular function, when all four responses to TOF stimulation can be felt, an estimation of the TOF ratio can be attempted. However, manual (tactile) evaluation of the response to TOF stimulation (Fig. 43.19) is not sensitive enough to exclude the possibility of residual neuromuscular block.[37,72,118,133] Greater sensitivity is achieved with $DBS_{3,3}$, but even absence of manual fade in the $DBS_{3,3}$ response does not exclude clinically significant residual block (i.e., TOF 0.6-0.9).[41,72] Moreover, some patients might suffer from residual block, even after recovery to a TOF ratio of 0.9 to 1.0.[77,81] Therefore, manual evaluation of responses to nerve stimulation should always be considered in relation to reliable clinical signs and symptoms of residual neuromuscular block (Box 43.1).

BOX 43.1 Clinical Tests of Postoperative Neuromuscular Recovery

Unreliable

- Sustained eye opening
- Protrusion of the tongue
- Arm lift to the opposite shoulder
- Normal tidal volume
- Normal or nearly normal vital capacity
- Maximum inspiratory pressure less than 40-50 cm H_2O

More Reliable, But Still Not Excluding Residual Neuromuscular Block

- Sustained head lift for 5 s
- Sustained leg lift for 5 s
- Sustained handgrip for 5 s
- Sustained "tongue depressor test"
- Maximum inspiratory pressure

When to Use a Peripheral Nerve Stimulator

In clinical practice, significant residual block can be excluded with certainty only if an objective method of neuromuscular monitoring is used.[78,79] Therefore, good evidence-based practice dictates that clinicians should always quantitate the extent of neuromuscular recovery by objective monitoring.[7-13] Only a TOF ratio of 0.90 to 1.00 measured by objective monitoring ensures a low risk of clinically significant residual block.

However, in many departments, clinicians do not have access to equipment for measuring the degree of block.[134] How then to evaluate and, as far as possible, exclude a clinically significant postoperative block? First, long-acting neuromuscular blocking drugs should not be used. Second, the tactile response to TOF nerve stimulation should be evaluated during surgery. Third, if possible, total twitch suppression should be avoided. The neuromuscular block should be managed so that there are always one or two tactile TOF responses. Fourth, the block should be antagonized at the end of the procedure, preferably with sugammadex if rocuronium or vecuronium have been used. When using neostigmine, reversal should not be initiated before at least two to four responses to TOF stimulation are present. Fifth, during recovery, tactile evaluation of the response to DBS is preferable to tactile evaluation of the response to TOF stimulation because it is easier to manually assess fade in the DBS than in the TOF response. Sixth, the clinician should recognize that the absence of tactile fade in both the TOF and DBS responses does not exclude significant residual block. Finally, reliable clinical signs and symptoms of residual block (see Box 43.1) should be considered in relation to the response to nerve stimulation. Fig. 43.20 shows how to minimize the risk of residual block with or without objective monitoring.[135]

In view of the uncertainty connected with the use of clinical tests of postoperative neuromuscular recovery and tactile evaluation of the response to nerve stimulation, all patients receiving neuromuscular blocking drugs should be monitored with an objective monitor. Whether the functioning of such a neuromuscular transmission analyzer is based on EMG, MMG, AMG, CPM, CMG, or PMG is not crucial as long as the apparatus is used appropriately.

Acknowledgment

The editors, publisher, and Dr. Casper Claudius would like to thank Dr. Jorgen Viby-Mogensen for his contribution to this chapter in the prior edition of this work. It has served as the foundation of the current chapter.

Reversal when *quantitative* (objective) neuromuscular monitoring is available and reliable
Reversal with sugammadex (SUG)
Reversal with neostigmine (NEO)
No response to TOF
TOF count 1–4
TOF ratio < 1.0
TOF ≥ 0.9
TOF 0.4–0.9
TOF < 0.4 or TOF count 2–3
TOF 0–1
PTC 0
PTC 1–15
TOF < 0.9
TOF ≥ 0.9
SUG 16 mg/kg
SUG 4 mg/kg
SUG 2 mg/kg
SUG 2 mg/kg
No reversal
NEO 0.02 mg/kg
NEO 0.05 mg/kg
Delay reversal to the TOF count of 2
Reversal when *peripheral* (subjective) nerve stimulator is available only or quantitative neuromuscular monitoring is unreliable
Reversal with sugammadex (SUG)
Reversal with neostigmine (NEO)
No response to TOF
TOF count 1–4 with or without fade
No response to TOF
TOF count 2–3
TOF count 4
PTC 0
PTC 1–15
With fade
Without fade
SUG 16 mg/kg
SUG 4 mg/kg
SUG 2 mg/kg
Delay reversal to the TOF count of 2
NEO 0.05 mg/kg
NEO 0.04 mg/kg
NEO 0.02 mg/kg

Fig. 43.20 Suggestion to diminish the incidence of residual curarization by neostigmine (NEO) or sugammadex (SUG) according to the level of block, determined with a nerve stimulator (quantitative or peripheral). Note that only a quantitative measured TOF ratio of 0.90 to 1.00 ensures low risk of clinically significant residual block. *PTC,* Posttetanic count; *TOF,* train-of-four. 44 Airway Management in the Adult

CARLOS A. ARTIME and CARIN A. HAGBERG

KEY POINTS

- One of the fundamental responsibilities of the anesthesiologist is to mitigate the adverse effects of anesthesia on the respiratory system by maintaining airway patency and ensuring adequate ventilation and oxygenation. The term *airway management* refers to this practice and is a cornerstone of anesthesia.
- Successful airway management requires a range of knowledge and skill sets—specifically, the ability to predict difficulty with airway management and to formulate an airway management strategy, as well as the skills to execute that strategy using the wide array of airway devices available.
- The American Society of Anesthesiologists' *Practice Guidelines for Management of the Difficult Airway* and the accompanying Difficult Airway Algorithm provide guidelines for the evaluation of the airway and preparation for difficult airway management and can guide clinical decision making when an anesthesiologist is faced with a known or potentially difficult airway. Cognitive aids, such as the Vortex approach, are useful to help implement airway algorithms in an emergency situation.
- A detailed understanding of airway anatomy is essential for the anesthesia provider.
- A complete evaluation of the airway and knowledge of difficult airway predictors can alert the anesthesiologist to the potential for difficulty with airway management and allow for appropriate planning.
- Apneic oxygenation can be used to prolong the duration of apnea without desaturation and is increasingly being adopted during the management of both difficult and routine airways.
- Application of local anesthesia to the airway or induction of general anesthesia is usually required to facilitate airway management, to provide comfort for the patient, and to blunt airway reflexes and the hemodynamic response to airway instrumentation.
- Over the past 30 years, the laryngeal mask airway (LMA) has emerged as one of the most important developments in airway devices.
- Tracheal intubation establishes a definitive airway, provides maximal protection against aspiration of gastric contents, and allows for positive-pressure ventilation with higher airway pressures than via a face mask or supraglottic airway.
- Flexible scope intubation of the trachea in an awake, spontaneously ventilating, and cooperative patient is the *gold standard* for the management of the difficult airway.
- Invasive airways are indicated as a rescue technique when attempts at establishing a noninvasive airway fail. The anesthesia practitioner should become proficient with techniques for transtracheal jet ventilation and cricothyrotomy.
- Extubation is a critical component of airway management with the potential for significant complications. The plan for extubation of the trachea must be preemptively formulated and includes a strategy for reintubation should the patient be unable to maintain an adequate airway after extubation.

Introduction

General anesthesia is associated with various effects on the respiratory system, including the loss of airway patency, loss of protective airway reflexes, and hypoventilation or apnea. Therefore one of the fundamental responsibilities of the anesthesiologist is to establish airway patency and to ensure adequate ventilation and oxygenation. The term *airway management* refers to the practice of establishing and securing a patent airway and is a cornerstone of anesthetic practice. Traditionally, ventilation via a mask and tracheal intubation have been the foundation of airway management; however, in the past 30 years, the laryngeal mask airway (LMA) has emerged as one of the most important developments in airway devices.

Because failure to secure a patent airway can result in hypoxic brain injury or death in only a few minutes, difficulty with airway management has potentially grave implications. Analysis of the American Society of Anesthesiologists (ASA) Closed Claims Project database has demonstrated that the development of an airway emergency increases the odds of death or brain damage by 15-fold.[1]

Although the proportion of claims attributable to airway-related complications has decreased over the past 3 decades, airway complications are still the second-most common cause of claims.[2] In 2011, the Royal College of Anaesthetists and the Difficult Airway Society (DAS) of the United Kingdom reported the results of the 4th National Audit Project (NAP4), a 1-year audit aimed at determining the incidence of major complications of airway management in anesthesia. NAP4 identified 133 major airway-related events in the perioperative period resulting in 16 deaths—a mortality incidence of 1 per 180,000 anesthetics—a number that could be as high as 1 per 50,000 anesthetics when underreporting is considered.[3] The most common airway problems in the NAP4 study were failure, delay, or difficulty in securing the airway; aspiration of gastric contents; and extubation-related complications. Poor assessment of the airway, poor planning, and a lack of personal and/or institutional preparedness for managing difficulty with airway management were the most common contributing factors.[4]

Studies such as these highlight the importance of successful airway management, which requires a range of knowledge and skill sets—specifically, the ability to predict difficulty with airway management, to formulate an airway management strategy, and to have the skills necessary to execute that strategy using the wide array of available airway devices.[5] Development of these skills should be an ongoing endeavor for all anesthesiologists. As with any manual skill, continued practice improves performance and may reduce the likelihood of complications. New airway devices are continually being introduced into the clinical arena, each with unique properties that may be advantageous in certain situations. Becoming familiar with new devices under controlled conditions is important for the anesthesia practitioner—the difficult airway is not an appropriate setting during which to experiment with a new technique.

ALGORITHMS FOR MANAGEMENT OF THE DIFFICULT AIRWAY

The American Society of Anesthesiologists Algorithm

In 1993, the ASA published the first *Practice Guidelines for Management of the Difficult Airway*, which was written with the intent to "facilitate the management of the difficult airway and to reduce the likelihood of adverse outcomes."[6] The most recent update to this report, published in 2013, defines the difficult airway as "the clinical situation in which a conventionally trained anesthesiologist experiences difficulty with ventilation of the upper airway via a mask, difficulty with tracheal intubation, or both" and provides guidelines for the evaluation of the airway and preparation for difficult airway management, including a Difficult Airway Algorithm (DAA) intended to guide clinical decision making when an anesthesiologist is faced with a known or potential difficult airway (Fig. 44.1).[7] The ASA DAA begins with a consideration of the relative clinical merits and feasibility of four basic management choices: (1) awake intubation versus intubation after induction of general anesthesia, (2) noninvasive techniques versus invasive techniques (i.e., surgical or percutaneous airway) for the initial approach to intubation, (3) video-assisted laryngoscopy (VAL) as an initial approach to intubation, and (4) preservation versus ablation of spontaneous ventilation.

The ASA DAA does not follow a linear decision-making tree, as the advanced cardiac life support (ACLS) algorithms do. It can be better understood and remembered by considering it as three separate scenarios: (1) predicted difficult airway (awake intubation), (2) difficult intubation with adequate oxygenation/ventilation (the "*non-emergency*" pathway), and (3) difficult intubation without adequate oxygenation/ventilation (the "cannot intubate, cannot oxygenate" [CICO] scenario or the "*emergency*" pathway).

Other Difficult Airway Algorithms

In addition to the ASA, several different national anesthesia societies have published their own guidelines for management of the difficult airway, including the Difficult Airway Society (DAS) from the United Kingdom,[8] the Canadian Airway Focus Group (CAFG),[9,10] the French Society of Anesthesia and Intensive Care (SFAR),[11] the German Society of Anesthesiology and Intensive Care Medicine (DGAI),[12] the Italian Society for Anesthesia and Intensive Care (SIAARTI),[13] and the Japanese Society of Anesthesiologists.[14] All of these include recommendations for the prediction of the difficult airway and suggest awake intubation as a management strategy (with the exception of the DAS guidelines) and all incorporate algorithms for both unanticipated difficult intubation with adequate oxygenation and the CICO scenario. Common elements include a focus on awakening the patient in the setting of a difficult intubation with adequate ventilation, the use of the LMA as a rescue for difficult mask ventilation, and emergency front of neck access (FONA) in the CICO scenario. The primary differences in these algorithms are in specific details, such as the number of intubation attempts suggested, the specific alternate devices recommended for difficult intubation, and the organization of the algorithm.[15]

Human Factors and Cognitive Aids

There has been growing attention to the influence of "human factors" on difficult airway management—namely, human behaviors, abilities, shortcomings, and biases as well as individual and team performance. Studies such as NAP4 have shown that these human factors contribute to an adverse airway outcome in over 40% of cases.[3] The use of airway checklists, preprocedural team briefings, and cognitive aids are all strategies for addressing human factor challenges.[16]

The Vortex approach, conceived by Dr. Nicholas Chrimes, a specialist anaesthetist in Melbourne, Australia, is one such cognitive aid designed to facilitate management of the unanticipated difficult airway.[17] Rather than relying on complex algorithms that are based on decision trees, the Vortex model utilizes a visual aid in the shape of a funnel or vortex (Fig. 44.2) to guide the airway practitioner through the three basic nonsurgical airway techniques (face-mask ventilation, supraglottic airway [SGA], and tracheal intubation). If after an "optimal attempt" at each of these nonsurgical modalities alveolar oxygen delivery has not been achieved, then one "travels down the vortex," and an emergency surgical airway is indicated. Because this strategic approach is more conceptual, it is simple enough to be utilized and recalled during a stressful airway emergency.

Functional Airway Anatomy

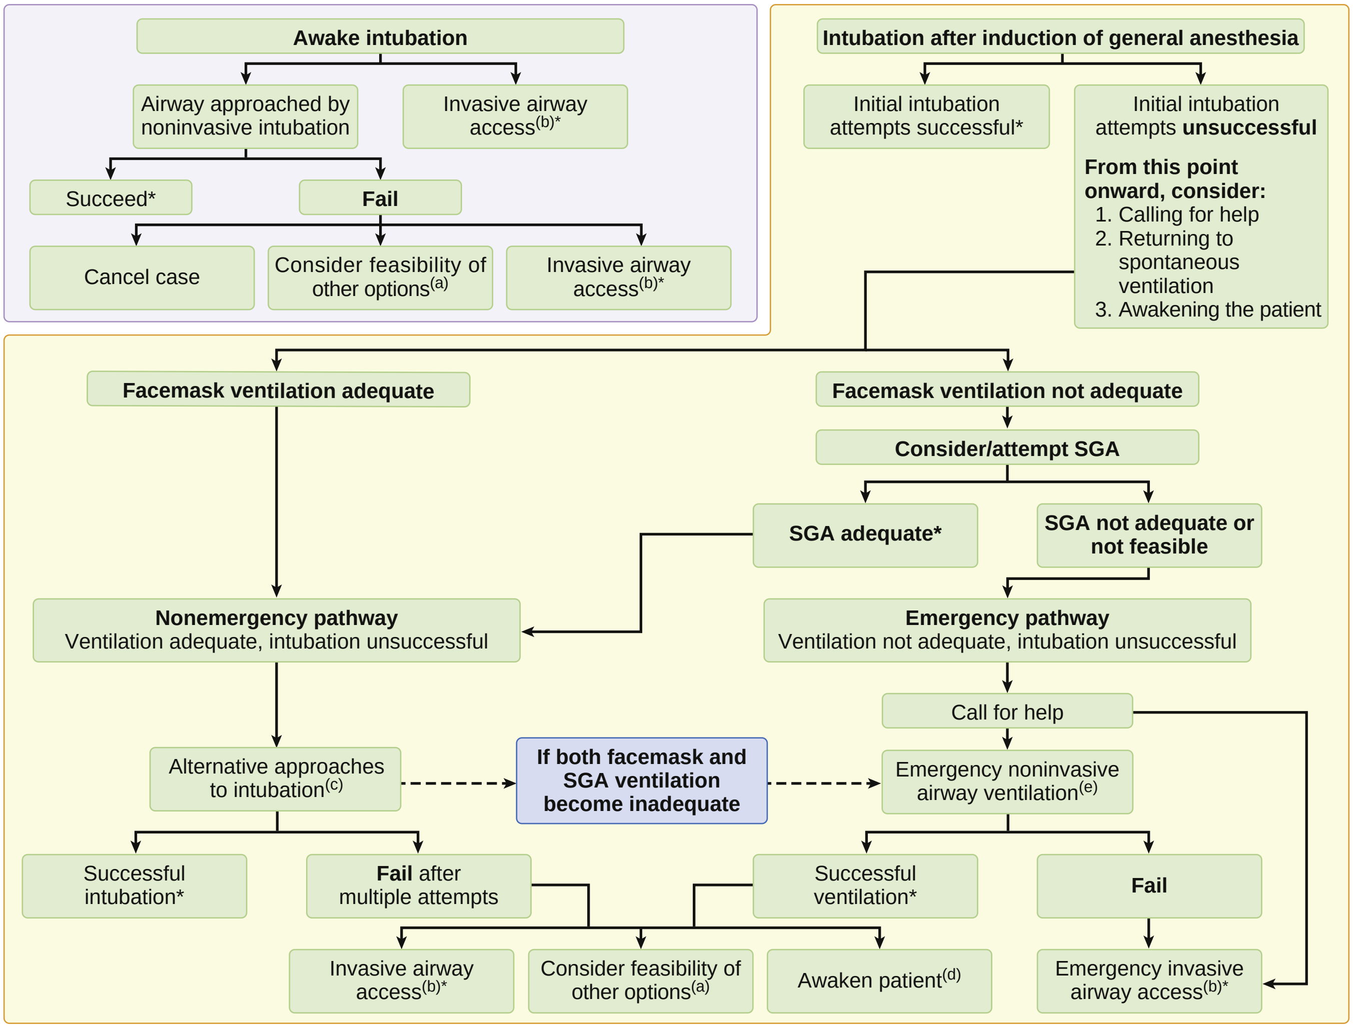
A detailed understanding of airway anatomy is essential for the anesthesiologist. Various aspects of airway

1. Assess the likelihood and clinical impact of basic management problems:
   - Difficulty with patient cooperation or consent
   - Difficult mask ventilation
   - Difficult supraglottic airway placement
   - Difficult laryngoscopy
   - Difficult intubation
   - Difficult surgical airway access

2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.

3. Consider the relative merits and feasibility of basic management choices:
   - Awake intubation *vs.* intubation after induction of general anesthesia
   - Noninvasive technique *vs.* invasive techniques for the initial approach to intubation
   - Video-assisted laryngoscopy as an initial approach to intubation
   - Preservation *vs.* ablation of spontaneous ventilation

4. Develop primary and alternative strategies:



Awake intubation
Airway approached by noninvasive intubation
Invasive airway access(b)*
Succeed*
Fail
Cancel case
Consider feasibility of other options(a)
Invasive airway access(b)*
Intubation after induction of general anesthesia
Initial intubation attempts successful*
Initial intubation attempts unsuccessful
From this point onward, consider:
1. Calling for help
2. Returning to spontaneous ventilation
3. Awakening the patient
Facemask ventilation adequate
Facemask ventilation not adequate
Consider/attempt SGA
SGA adequate*
SGA not adequate or not feasible
Nonemergency pathway
Ventilation adequate, intubation unsuccessful
Emergency pathway
Ventilation not adequate, intubation unsuccessful
Call for help
Alternative approaches to intubation(c)
If both facemask and SGA ventilation become inadequate
Emergency noninvasive airway ventilation(e)
Successful intubation*
Fail after multiple attempts
Successful ventilation*
Fail
Invasive airway access(b)*
Consider feasibility of other options(a)
Awaken patient(d)
Emergency invasive airway access(b)*

***Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO$_2$.**

a. Other options include (but are not limited to): surgery using facemask or supraglottic airway (SGA) anesthesia (e.g., LMA, ILMA, laryngeal tube), local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.

c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (e.g., LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Emergency noninvasive airway ventilation consists of a SGA.

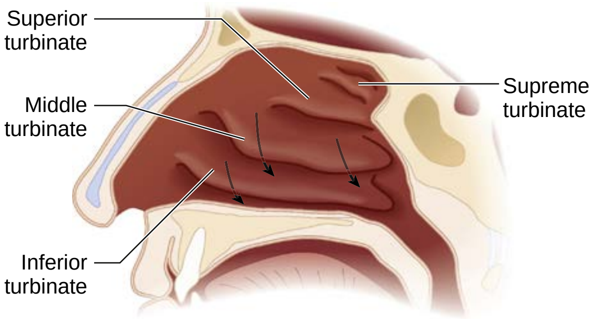
management depend on a working knowledge of the anatomy involved, including airway assessment, preparation of the airway for awake intubation, and the proper use of airway devices. Knowledge of normal anatomy and anatomic variations that may render airway management more difficult helps with the formulation of an airway management plan. Because some critical anatomic structures may be obscured during airway management, the anesthesiologist must be familiar with the interrelationship between different airway structures.

The airway can be divided into the upper airway, which includes the nasal cavity, the oral cavity, the pharynx, and the larynx; and the lower airway, which consists of the tracheobronchial tree.



Superior turbinate
Middle turbinate
Inferior turbinate
Supreme turbinate

Fig. 44.3 Lateral wall of the nasal cavity. (From Redden RJ. Anatomic considerations in anesthesia. In: Hagberg CA, ed. *Handbook of Difficult Airway Management*. Philadelphia: Churchill Livingstone; 2000, p. 3, Fig. 1.2.)

NASAL CAVITY

The airway begins functionally at the naris, the external opening of the nasal passages. The nasal cavity is divided into the right and left nasal passages (or fossae) by the nasal septum, which forms the medial wall of each passage. The septum is formed by the septal cartilage anteriorly and by two bones posteriorly—\the ethmoid (superiorly) and the vomer (inferiorly). Nasal septal deviation is common in the adult population[18]; therefore the more patent side should be determined before passing instrumentation through the nasal passages. The lateral wall of the nasal passages is characterized by the presence of three turbinates (or conchae) that divide the nasal passage into three scroll-shaped meatuses (Fig. 44.3). The inferior meatus, between the inferior turbinate and the floor of the nasal cavity, is the preferred pathway for passage of nasal airway devices[19]; improper placement of objects in the nose can result in avulsion of a turbinate.[20,21] The roof of the nasal cavity is formed by the cribriform plate, part of the ethmoid bone. This fragile structure, if fractured, can result in communication between the nasal and intracranial cavities and a resultant leakage of cerebrospinal fluid. Because the mucosal lining of the nasal cavity is highly vascular, vasoconstrictor should be applied, usually topically, before instrumentation of the nose to minimize epistaxis. The posterior openings of the nasal passages are the choanae, which lead into the nasopharynx.

ORAL CAVITY

Because of the relatively small size of the nasal passages and the significant risk of trauma, the mouth is often used as a conduit for airway devices. Many airway procedures require adequate mouth opening, which is accomplished by rotation within the temporomandibular joint (TMJ) and subsequent opening by sliding (also known as *protrusion* or *subluxation*) of the condyles of the mandible within the TMJ.[22]

The oral cavity leads to the oropharynx and is inferiorly bounded by the tongue and superiorly by the hard and soft palates. The hard palate, formed by parts of the maxilla and the palatine bone, makes up the anterior two thirds of the roof of the mouth; the soft palate (velum palatinum), a fibromuscular fold of tissue attached to the hard palate, forms the posterior one third of the roof of the mouth.

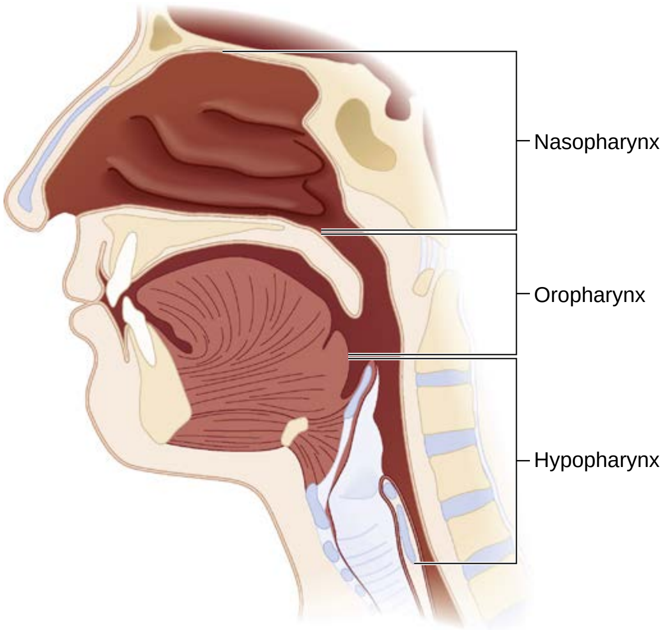


Fig. 44.4 **Sagittal section through the head and neck showing the subdivisions of the pharynx.** (From Redden RJ. Anatomic considerations in anesthesia. In: Hagberg CA, ed. *Handbook of Difficult Airway Management*. Philadelphia: Churchill Livingstone; 2000, p. 7, Fig. 1.6.)

The tongue is anchored to various structures by its extrinsic musculature; of these, the most clinically relevant to the anesthesiologist is the genioglossus, which connects the tongue to the mandible. The jaw-thrust maneuver uses the sliding component of the TMJ to move the mandible and the attached tongue anteriorly, thereby relieving airway obstruction caused by the posterior displacement of the tongue into the oropharynx.[22]

Beneath the tongue, the mylohyoid muscles separate the floor of the mouth into the sublingual space superiorly and the submental space inferiorly. Cellulitis (Ludwig's angina) or hematoma formation in these spaces can cause elevation and posterior displacement of the tongue and resultant airway obstruction.[23]

PHARYNX

The pharynx is a muscular tube that extends from the base of the skull down to the level of the cricoid cartilage and connects the nasal and oral cavities with the larynx and esophagus. The posterior wall of the pharynx is made up of the buccopharyngeal fascia, which separates the pharynx from the retropharyngeal space. Improper placement of a gastric or tracheal tube can result in laceration of this fascia and the formation of a retropharyngeal dissection.[24,25] The pharyngeal musculature in the awake patient helps maintain airway patency; loss of pharyngeal muscle tone is one of the primary causes of upper airway obstruction during anesthesia.[26,27] A chin lift with mouth closure increases longitudinal tension in the pharyngeal muscles, counteracting the tendency of the pharyngeal airway to collapse.[28]

The pharynx can be divided into the nasopharynx, the oropharynx, and the hypopharynx (Fig. 44.4). Along the superior and posterior walls of the nasopharynx are the adenoid tonsils, which can cause chronic nasal obstruction and, when enlarged, can cause difficulty passaging airway devices. The nasopharynx ends at the soft palate; this region is termed the *velopharynx* and is a common site of airway obstruction in both awake and anesthetized patients.[26] The oropharynx begins at the soft palate and extends inferiorly to the level of the epiglottis. The lateral walls contain the palatoglossal folds and the palatopharyngeal folds, also termed the *anterior* and *posterior faucial* (tonsillar) *pillars*, respectively; these folds contain the palatine tonsils, which can hypertrophy and cause airway obstruction (Fig. 44.5). The base of the tongue lies in the anterior aspect of the oropharynx, connected to the epiglottis by the glossoepiglottic folds, which bound paired spaces known as the *valleculae* (although these are frequently referred to as a single space called the *vallecula*). The hypopharynx begins at the level of the epiglottis and terminates at the level of the cricoid cartilage, where it is continuous with the esophagus. The larynx protrudes into the hypopharynx, creating two piriform recesses on either side (Fig. 44.6).

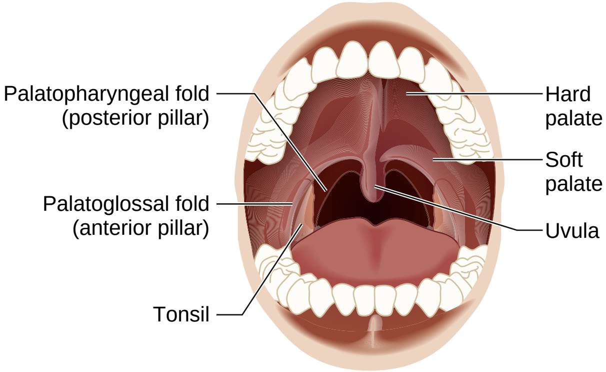

Fig. 44.5 **Oral cavity and oropharynx.** (From Redden RJ. Anatomic considerations in anesthesia. In: Hagberg CA, ed. *Handbook of Difficult Airway Management*. Philadelphia: Churchill Livingstone; 2000, p. 8, Fig. 1.7.)

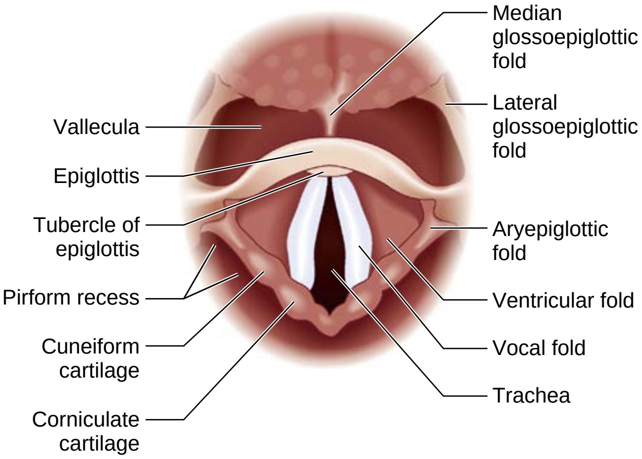

Fig. 44.6 **Larynx as visualized from the hypopharynx.** (From Redden RJ. Anatomic considerations in anesthesia. In: Hagberg CA, ed. *Handbook of Difficult Airway Management*. Philadelphia: Churchill Livingstone; 2000, p. 8, Fig. 1.8.)

LARYNX

The larynx is a complex structure of cartilage, muscles, and ligaments that serves as the inlet to the trachea and

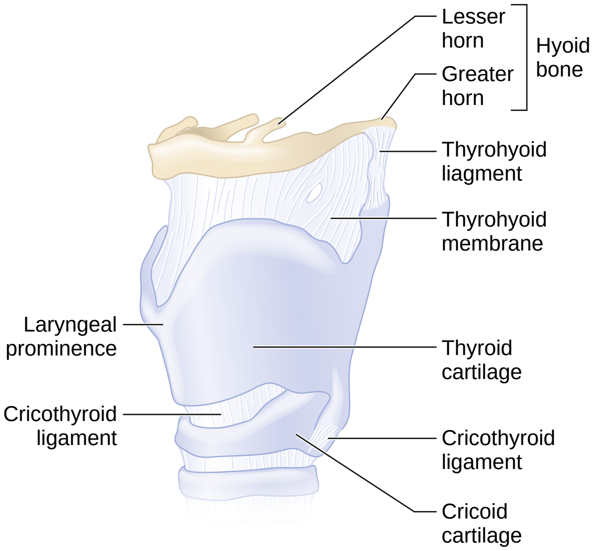

Fig. 44.7 Cartilaginous and membranous components of the larynx. (From Redden RJ. Anatomic considerations in anesthesia. In: Hagberg CA, ed. *Handbook of Difficult Airway Management*. Philadelphia: Churchill Livingstone; 2000, p. 10, Fig. 1.9.)

performs various functions, including phonation and airway protection. The cartilaginous framework of the larynx is made up of nine separate cartilages: the thyroid and cricoid cartilages; the paired arytenoid, corniculate, and cuneiform cartilages; and the epiglottis. They are joined by ligaments, membranes, and synovial joints, and are suspended by the hyoid bone via the thyrohyoid ligaments and membrane (Fig. 44.7).

The thyroid cartilage is the largest of these cartilages and supports most of the soft tissues of the larynx. The superior thyroid notch and the associated laryngeal prominence (*Adam's apple*) are appreciable from the anterior neck and serve as important landmarks for percutaneous airway techniques and laryngeal nerve blocks. The cricoid cartilage, at the level of the sixth cervical vertebra, is the inferior limit of the larynx and is anteriorly connected to the thyroid cartilage by the cricothyroid membrane (CTM). It is the only complete cartilaginous ring in the airway. The arytenoid cartilages articulate with the posterior cricoid and are the posterior attachments for the vocal cords.

When viewed from the pharynx, as during direct laryngoscopy (DL), the larynx begins at the epiglottis, which is a cartilaginous flap that serves as the anterior border of the laryngeal inlet. It functions to divert food away from the larynx during the act of swallowing, although its role in this regard is not essential to prevent tracheal aspiration.[29] The anterior surface of the epiglottis is attached to the upper border of the hyoid bone by the hyoepiglottic ligament. The laryngeal inlet is bound laterally by the aryepiglottic folds, and posteriorly by the corniculate cartilages and the interarytenoid notch (see Fig. 44.6).

The space inferior to the laryngeal inlet down to the inferior border of the cricoid cartilage is the laryngeal cavity. The ventricular folds (also referred to as the *vestibular folds* or *false vocal cords*) are the most superior structure within the laryngeal cavity. Beneath these are the true vocal cords, which attach to the arytenoids posteriorly and the thyroid cartilage anteriorly, where they join together to form the anterior commissure. The space between the vocal cords is termed the *glottis*; the portion of the laryngeal cavity above the glottis is known as the *vestibule*, and the portion inferior to the vocal cords is known as the *subglottis*.

TRACHEA AND BRONCHI

The trachea begins at the level of the cricoid cartilage and extends to the carina at the level of the fifth thoracic vertebra; this length is 10 to 15 cm in the adult. It consists of 16 to 20 C-shaped cartilaginous rings that open posteriorly and are joined by fibroelastic tissue; the trachealis muscle forms the posterior wall of the trachea. At the carina, the trachea bifurcates into the right and left mainstem bronchi. In the adult, the right mainstem bronchus branches off at a more vertical angle than the left mainstem bronchus, resulting in a greater likelihood of foreign bodies and endotracheal tubes (ETTs) entering the right bronchial lumen.[30]

Airway Assessment

Although the anesthesia provider should always be prepared for potential difficulty with airway management, the ability to predict the difficult airway in advance is obviously desirable. Certain physical findings or details from the patient's history can be prognostic of difficulty with mask ventilation, supraglottic airway placement, laryngoscopy, tracheal intubation, or the performance of a surgical airway. No single test has been devised to predict a difficult airway accurately 100% of the time; however, a complete evaluation of the airway and knowledge of the difficult airway predictors can alert the anesthesiologist to the potential for difficulty and allow for appropriate planning.

TRADITIONAL METRICS

Airway assessment should begin with a directed patient history whenever possible.[7] One of the most predictive factors for difficult intubation is a history of previous difficulty with intubation.[31] On the other hand, a history of a previously easy airway does not rule out the possibility of difficulty with ventilation or intubation. In either case, the patient interview should specifically address changes in weight, symptomatology, and pathologic conditions since the last induction of an anesthetic (if there was one), and attempts should be made at obtaining prior anesthetic records—they may yield useful information concerning airway management. The presence of pathologic states that increase the risk of a difficult airway should be elicited by performing a medical history. A focused review of systems can alert the anesthesiologist to other potential factors that may predict difficult airway management; for example, a history of snoring has been shown to be predictive of difficult mask ventilation.[32,33]

A physical examination of the airway should be preoperatively performed, when possible, to detect any physical characteristics that may suggest a difficult airway.[7] The specific characteristics that should be evaluated in this examination are listed in Box 44.1.

The visual inspection of the face and neck should focus on any physical characteristics that may indicate the potential

BOX 44.1 Components of the Physical Examination of the Airway

- Visual inspection of the face and neck
- Assessment of mouth opening
- Evaluation of oropharyngeal anatomy and dentition
- Assessment of neck range of motion (ability of the patient to assume the sniffing position)
- Assessment of the submandibular space
- Assessment of the patient's ability to slide the mandible anteriorly (test of mandibular prognathism)

for difficulty with airway management. These include obvious facial deformities, neoplasms involving the face or neck, facial burns, a large goiter, a short or thick neck, or a receding mandible. The presence of a beard has been shown to be associated with difficult ventilation attributable to the difficulty in obtaining a mask seal.[32,33] Cervical collars or cervical traction devices can interfere with both mask ventilation and DL. A neck circumference greater than 43 cm (17 inches) is associated with difficulty with tracheal intubation[34]; Brodsky demonstrated that a large neck circumference is, in fact, more predictive of difficulty with tracheal intubation than a high body mass index (BMI).[35]

Assessment of mouth opening and inspection of the oropharyngeal anatomy is achieved by instructing the patient to open his or her mouth as wide as possible. An interincisor distance of less than 3 cm (or 2 fingerbreadths), as measured from the upper to the lower incisors with maximal mouth opening, can suggest the possibility of difficult intubation[7]; some studies have used 4 or 4.5 cm as the cutoff.[36] A thorough inspection of the oropharynx can help identify pathologic characteristics that may result in difficulty with intubation, such as neoplasm, a high arched palate, or macroglossia. In 1983, Mallampati and associates described a clinical sign to predict difficult tracheal intubation based on the size of the base of the tongue.[37] A Mallampati classification of I to III is assigned, based on the visibility of the faucial pillars, uvula, and soft palate when the patient is seated upright with the head neutral, the mouth open, the tongue protruded, and no phonation.[38] Higher scores on the Mallampati classification indicate poor visibility of the oropharyngeal structures attributable to a large tongue relative to the size of the oropharyngeal space, and, subsequently, a more difficult laryngoscopy. The modified Mallampati classification described by Samsoon and Young,[39] which adds a fourth classification, is the most commonly used airway assessment test in current anesthesia practice and is defined as follows (Fig. 44.8):

- Class I: Faucial pillars, uvula, and soft palate are visualized.
- Class II: Base of the uvula and soft palate are visualized.
- Class III: Soft palate only is visualized.
- Class IV: Hard palate only is visualized.

As a stand-alone test, the modified Mallampati classification is insufficient for accurate prediction of difficult intubation; however, it may have clinical utility in combination with other difficult airway predictors.[40] Some studies support obtaining a Mallampati score with the head in full extension to improve the predictive value of the test.[38,41]

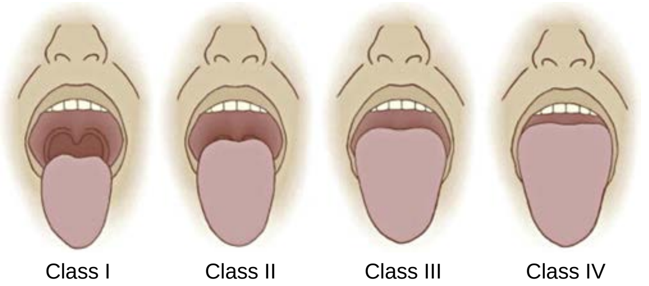

Fig. 44.8 Modified Mallampati classification as described by Samsoon and Young. Classes are differentiated on the basis of the structures visualized: class I—soft palate, fauces, uvula, tonsillar pillars; class II—soft palate, fauces, uvula; class III—soft palate, base of the uvula; class IV—soft palate not visible. (From Mallampati SR. Recognition of the difficult airway. In: Benumof JL, ed. *Airway Management Principles and Practice.* St Louis: Mosby; 1996, p. 132.)

A Mallampati *zero* classification has been proposed when the epiglottis can be visualized during examination of the oropharynx; this finding is usually associated with easy laryngoscopy,[42,43] although difficulty with airway management attributable to a large, floppy epiglottis in patients with a Mallampati zero classification can occur.[44,45]

An examination of dentition should be performed when the oropharyngeal anatomy is being evaluated.[7] Relatively long upper incisors can impair DL. Poor dentition and loose teeth increase the risk of dental trauma and present a risk of tooth dislodgment with subsequent aspiration; very loose teeth should be removed before laryngoscopy. Cosmetic dental work, such as veneers, caps, crowns, and bridges, are particularly susceptible to damage during airway management. Edentulousness is predictive of easy tracheal intubation but potentially difficult mask ventilation.[46]

The ideal positioning for DL is achieved by cervical flexion and atlantooccipital extension and is most commonly referred to as the *sniffing position*[47] (see Direct Laryngoscopy: Preparation and Positioning). Assessment of a patient's ability to assume this position should be included in the airway examination; an inability to extend the neck at the atlantooccipital joint is associated with difficult intubation.[48] Head and neck mobility can also be quantitatively assessed by measuring the sternomental distance between the sternal notch and the point of the chin with the head in full extension and the mouth closed. Distances less than 12.5 cm are associated with difficult intubation.[49] An assessment of overall neck range of motion can be performed by measuring the angle created by the forehead when the neck is fully flexed and then fully extended; a measurement of less than 80 degrees is predictive of difficult intubation.[50]

During DL, the tongue is displaced into the submandibular space; glottic visualization may be inadequate if this space is diminished because of a small mandible. This scenario is frequently referred to as an *anterior larynx*. A thyromental distance of less than 6.5 cm (3 fingerbreadths), as measured from the thyroid notch to the lower border of the mentum, is indicative of reduced mandibular space and may predict difficulty with intubation.[36,49] Compliance of this space should also be assessed; a lack of compliance or the presence of a mass is a nonreassuring finding.[7]

Tests of the ability for mandibular protrusion (prognathism) have predictive value and should be included in the airway assessment. The inability to extend the lower incisors beyond the upper incisors may be indicative of difficult laryngoscopy.[51] A similar evaluation, the upper lip bite test (ULBT) described by Khan and colleagues, has been shown to predict difficult laryngoscopy with higher specificity and less interobserver variability than the Mallampati classification; an inability of the lower incisors to bite the upper lip is associated with more difficult laryngoscopy.[52,53]

Although individual airway tests are limited by low sensitivity and positive predictive value, some multivariable assessments have been shown to have higher predictive power. The Mallampati score has been shown to have improved predictive value when combined with thyromental, sternomental, and/or interincisor distances.[49] Models that use several risk factors, such as the Wilson risk sum score (weight, head and neck movement, jaw movement, receding mandible, and buck teeth) and the El-Ganzouri risk index (mouth opening, thyromental distance, Mallampati class, neck movement, prognathism, weight, and history of difficult intubation) have been developed in an attempt to improve the predictive value of airway assessment.[50,54] On the other hand, a recent large database study of an airway risk index that utilizes seven independent risk factors found that it does not improve prediction of difficult intubation.[55] Langeron and associates developed a computer-assisted model that uses complex interactions among several risk factors (BMI, mouth opening, thyromental distance, Mallampati class, and receding mandible) to predict difficult intubation more accurately than other models based on simpler statistical analyses.[56]

NEW MODALITIES

Owing to the poor sensitivity and specificity of traditional metrics for airway assessment, a number of new modalities are being studied. The use of point-of-care ultrasonography for the prediction of difficult laryngoscopy and intubation has shown some promise in small studies, but its overall value has yet to be established.[57] Computed tomographic images of the head and neck can be used to create three-dimensional virtual endoscopic images that can be used for planning difficult airway management, particularly for patients with complex airway pathology.[58] Early studies of facial image analysis have also shown promise for the use of this technology in predicting difficult intubation.[59]

Physiologic Concepts for Airway Management

PREOXYGENATION

With the induction of anesthesia, hypoxemia can quickly develop as a result of hypoventilation or apnea in combination with decreases in functional residual capacity (FRC) attributable to the supine position, muscle paralysis, and the direct effects of the anesthetic agents themselves. Preoxygenation, the process of replacing nitrogen in the lungs with oxygen, provides an increased length of time before hemoglobin desaturation occurs in an apneic patient. This lengthened *apnea time* provides an improved margin of safety while the anesthesiologist secures the airway and resumes ventilation. Adequate preoxygenation is essential when mask ventilation after the induction of anesthesia is contraindicated or anticipated to be difficult, when intubation is anticipated to be difficult, and in patients with a smaller FRC (i.e., patients who are obese or pregnant).[60] Because difficulty with airway management can unexpectedly occur, routine preoxygenation before induction of general anesthesia is recommended.[61]

Preoxygenation is typically performed via a face mask attached to either the anesthesia machine or a Mapleson circuit. To ensure adequate preoxygenation, 100% oxygen must be provided at a flow rate high enough to prevent rebreathing (10 to 12 L/min), and no leaks around the face mask must be present. An end-tidal concentration of oxygen greater than 90% is considered to maximize apnea time. With maximal preoxygenation, the time to oxyhemoglobin desaturation below 80% can vary from 9 minutes in a healthy, nonobese adult to 3 minutes or less in children or obese adults.[62]

Two primary methods are used to accomplish preoxygenation. The first method uses tidal volume ventilation through the face mask for 3 minutes, which allows the exchange of 95% of the gas in the lungs.[60] The second method uses vital capacity breaths to achieve adequate preoxygenation more rapidly. Four breaths over 30 seconds is not as effective as the tidal volume method but may be acceptable in certain clinical situations; eight breaths over 60 seconds has been shown to be more effective.[60]

Transnasal humidified rapid-insufflation ventilatory exchange (THRIVE) at 60 L/min for 3 minutes has been demonstrated to be as effective as tidal volume preoxygenation by face mask (see Apneic Oxygenation).[63] Head-up positioning has been shown to improve the quality of preoxygenation in both obese[64] and nonobese patients.[65] The use of noninvasive positive-pressure ventilation (PPV) for preoxygenation also prolongs apnea time.[66,67]

APNEIC OXYGENATION

Apneic oxygenation is a physiologic phenomenon by which oxygen from the oropharynx or nasopharynx diffuses down into the alveoli as a result of the net negative alveolar gas exchange rate resulting from oxygen removal and carbon dioxide excretion during apnea. Assuming the airway is patent and oxygen is insufflated through the nose and/or mouth, oxygenation occurs, prolonging apnea time beyond that of standard face-mask preoxygenation.[68]

Oxygen can be insufflated at up to 15 L/min with nasal cannulae (nasal oxygen during efforts securing a tube [NO DESAT])[69] or with a catheter placed through the nose or mouth with the tip in the pharynx (pharyngeal oxygen insufflation).[70] Studies have demonstrated that these techniques are effective in delaying oxyhemoglobin desaturation in morbidly obese patients[71,72] and during emergency tracheal intubation.[73,74]

THRIVE involves the administration of warmed, humidified oxygen, allowing higher oxygen flow rates than the previously described techniques—up to 70 L/min. These higher flows extend the apnea time even further and improve the clearance of carbon dioxide, preventing the potential development of severe respiratory acidosis. In 25 patients with a difficult airway at risk for rapid desaturation, THRIVE was used to achieve a median apnea time of 14 minutes, with a range of 5 to 65 minutes, and an average rate of carbon dioxide rise of only 1.1 mm Hg per minute.[63]

PULMONARY ASPIRATION OF GASTRIC CONTENTS

In 1946, Mendelson was the first to describe aspiration pneumonitis attributable to the pulmonary aspiration of acidic gastric secretions in pregnant women undergoing anesthesia.[75] This potentially fatal complication, occasionally referred to as Mendelson syndrome, has since been the intense focus of preventive efforts among the anesthesia community. Prevention of aspiration of gastric contents is primarily accomplished by adherence to established preoperative fasting guidelines, premedication with drugs that may decrease the risk of aspiration pneumonitis, and specialized induction techniques, which are discussed later in this chapter.

Traditionally, patients who were scheduled for elective procedures requiring sedation, regional anesthesia, or general anesthesia were instructed to remain NPO (Latin for *nulla per os* or *nothing by mouth*) after midnight to ensure an empty stomach to decrease the risk of regurgitation. Based on evidence that allowing ingestion of clear liquids 2 to 4 hours before surgery resulted in lower gastric volumes and higher gastric pH, the ASA published *Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration* in 1999 that liberalized the traditional NPO policy and allowed clear liquids up to 2 hours before beginning elective procedures requiring anesthesia. The guidelines, most recently updated in 2017, recommend 4 hours of fasting from breast milk and 6 hours of fasting from solid foods, infant formula, and nonhuman milk.[76] Fried or fatty foods may require longer fasting times (e.g., 8 hours or more).[76] Although the ASA guidelines do not specifically address chewing gum, hard candies, or smoking, guidelines published by the European Society of Anaesthesiology on the topic do not recommend delaying the start of anesthesia if a patient has consumed any of these immediately before the induction of anesthesia.[77]

The routine use of drugs as prophylaxis against aspiration pneumonitis is not recommended by the ASA guidelines[76] but may be beneficial in patients with specific risk factors for aspiration, such as a full stomach, symptomatic gastroesophageal reflux disease (GERD), hiatal hernia, presence of a nasogastric tube, morbid obesity, diabetic gastroparesis, or pregnancy.[78,79] The goal of aspiration prophylaxis is twofold: to decrease gastric volume and to increase gastric fluid pH. Commonly used agents include nonparticulate antacids (e.g., Bicitra), promotility drugs (e.g., metoclopramide), and H_2-receptor antagonists. These drugs may be used alone or in combination.[80]

AIRWAY REFLEXES AND THE PHYSIOLOGIC RESPONSE TO INTUBATION OF THE TRACHEA

One of the most important teleologic functions of the larynx is that of airway protection, which is primarily provided by the glottic closure reflex. This reflex is triggered by sensory receptors in the glottic and subglottic mucosa and results in strong adduction of the vocal cords.[81] An exaggerated, maladaptive manifestation of this reflex, referred to as *laryngospasm*, is a potential complication of airway management. Laryngospasm is usually provoked by glossopharyngeal or vagal stimulation attributable to airway instrumentation or vocal cord irritation (e.g., from blood or vomitus) in the setting of a light plane of anesthesia (stage II of the Guedel classification), but it can also be precipitated by other noxious stimuli and can persist well after the removal of the stimulus. Treatment of laryngospasm includes removal of airway irritants, deepening of the anesthetic, and the administration of a rapid-onset neuromuscular blocking drug (NMBD), such as succinylcholine.[82] Continuous positive airway pressure with 100% oxygen is commonly cited as a therapeutic maneuver, although the pressure may push the aryepiglottic folds closer together and may actually promote laryngospasm by acting as a mechanical stimulus.[83,84] Bilateral pressure at the *laryngospasm notch* between the condyle of the mandible and the mastoid process can be effective at treating laryngospasm by causing an intense, painful stimulus, which may function to terminate laryngospasm by arousing a semiconscious patient or by activating autonomic pathways.[82]

The tracheobronchial tree also possesses reflexes to protect the lungs from noxious substances. Irritation of the lower airway by a foreign substance activates a vagal reflex–mediated constriction of bronchial smooth muscle, resulting in bronchospasm. Untreated bronchospasm can result in an inability to ventilate because of an extremely elevated airway resistance. Treatment includes a deepening of anesthetic with propofol or a volatile agent and the administration of inhaled β_2-agonist or anticholinergic medications. Administration of intravenous (IV) lidocaine has been studied, but the evidence does not support its use for treatment of bronchospasm.[85]

Tracheal intubation, as well as laryngoscopy and other airway instrumentation, provides an intense noxious stimulus via vagal and glossopharyngeal afferents that results in a reflex autonomic activation, which is usually manifested as hypertension and tachycardia in adults and adolescents; in infants and small children, autonomic activation may result in bradycardia. Hypertension and tachycardia are usually of short duration; however, they may have consequences in patients with significant cardiac disease. Central nervous system activation as a result of airway management results in increases in electroencephalographic (EEG) activity, cerebral metabolic rate, and cerebral blood flow, which may result in an increase in intracranial pressure in patients with decreased intracranial compliance.[85]

Anesthesia for Airway Management

To facilitate airway management, some form of anesthesia is usually required to provide comfort for the patient, to blunt airway reflexes, and to blunt the hemodynamic response to airway instrumentation. Most commonly, airway management is performed after induction of general anesthesia. Alternatively, an *awake* technique, which entails establishing an airway (including tracheal intubation) by using local anesthesia of the airway and/or sedation, can be used to meet these goals when clinically indicated. In emergency scenarios where the patient is obtunded or comatose, such as in the event of acute respiratory or cardiac arrest, anesthetic drugs may not be required.

AIRWAY MANAGEMENT AFTER THE INDUCTION OF GENERAL ANESTHESIA

Airway management is usually performed after the induction of general anesthesia if the anesthesiologist determines that it is safe to do so. Several pharmacologic techniques are used for the induction of anesthesia, each with its own implications for airway management. The decision of which induction technique to use should be made with careful consideration of the specific clinical circumstances at hand.

Standard Intravenous Induction with Neuromuscular Blockade

The most common technique for induction of general anesthesia is the standard IV induction, which entails the administration of a rapid-acting IV anesthetic, followed by an NMBD. Muscle relaxation achieved by the administration of NMBDs improves intubating conditions by facilitating laryngoscopy, preventing both reflex laryngeal closure and coughing after intubation.[22,86]

Propofol is the most frequently used IV anesthetic drug; other options include etomidate, ketamine, thiopental, and midazolam. The choice of drug depends on a variety of factors including the patient's hemodynamic status, comorbidities, and allergies, as well as drug pharmacokinetics, side effects, physician preference, and availability.[87] Whether the choice of an anesthetic drug has any effect on the quality of intubating conditions when NMBDs are also administered is not well established. Studies comparing propofol, etomidate, and thiopental in combination with NMBDs showed no difference in intubating conditions between the different anesthetics.[88,89] On the other hand, one study, during which patients received cisatracurium, showed that larger doses of propofol were associated with improved intubating conditions, as compared with smaller doses.[90]

For many years, succinylcholine was the most frequently used NMBD for routine IV induction[87]; however, nondepolarizing NMBDs have gained greater popularity attributable to the risk of adverse effects from succinylcholine administration, including bradycardia, myalgia, hyperkalemia, increased intracranial pressure, and increased intragastric pressure.[91] Succinylcholine, the only depolarizing NMBD in clinical use, has the benefit of a rapid onset combined with a short duration of action, and it is currently used most often when those properties are desired. Most notably, succinylcholine is still commonly used in the setting of a suspected difficult airway; its short duration of action theoretically allows for the resumption of spontaneous ventilation before severe hypoxia develops in a preoxygenated patient, although evidence suggests that this may not predictably occur.[92]

Nondepolarizing NMBDs are the more frequently used relaxants for routine IV induction of anesthesia.[91] The most commonly used nondepolarizing NMBDs in current practice—rocuronium, vecuronium, and cisatracurium—are notable for having a favorable safety profile with relatively few side effects. The primary limitation of these drugs is a significantly longer duration of action; once administered, a functional airway must be established within minutes to avoid life-threatening hypoxia. Sugammadex is a selective relaxant-binding agent for rocuronium that has the ability to reverse profound neuromuscular blockade rapidly in a time comparable with spontaneous recovery from succinylcholine (also see Chapter 28).[93]

Traditional teaching in the United States has advocated withholding NMBDs until the ability to mask ventilate has been established. If ventilation via a mask cannot be achieved, a preoxygenated patient can then theoretically resume spontaneous ventilation or be awakened before the onset of hypoxia.[94] This practice has been increasingly questioned in the literature in part because of a number of studies demonstrating that ventilation via a mask is *not* rendered more difficult by muscle relaxation[95,96]; rather, mask ventilation is, in fact, facilitated by muscle relaxation.[97] One issue with the traditional paradigm is that the theoretical advantage of the practice—the ability to awaken the patient if mask ventilation fails—is rarely used.[98] The desire to preserve that ability may, in fact, result in giving an inadequate dose of anesthetic during induction, resulting in a difficult mask ventilation situation when one would not have otherwise occurred.[98] Delaying the administration of NMBDs can result in the onset of hypoxia before spontaneous recovery (with succinylcholine) or reversal (with sugammadex) is possible.

The authors do not recommend withholding NMBDs in patients who are predicted to be easy to mask ventilate and/or intubate. For patients in whom difficulty with both mask ventilation and intubation are predicted, awake intubation or inhalation induction of anesthesia should be considered, and the administration of NMBDs is best withheld until the ability to ventilate is proven.

Rapid-Sequence Induction and Intubation

Rapid-sequence induction and intubation (often simply referred to as *rapid sequence induction* [RSI] in the anesthesia literature) is a specialized method of IV induction commonly used when an increased risk of gastric regurgitation and pulmonary aspiration of gastric contents exists. After adequate preoxygenation and while cricoid pressure is applied, an induction dose of IV anesthetic is rapidly followed by 1 to 1.5 mg/kg of IV succinylcholine, and the trachea is intubated without attempts at PPV. The goal is to achieve optimal intubating conditions rapidly to minimize the length of time between the loss of consciousness (LOC) and securing of the airway with a cuffed endotracheal tube (ETT). Cricoid pressure, eponymously referred to as the Sellick maneuver after the physician who first described it, involves the application of pressure at the cricoid ring to occlude the upper esophagus, thereby preventing the regurgitation of gastric contents into the pharynx.[99] The recommended force to be applied is 10 Newtons (N) while the patient is awake, increased to 30 N after LOC. These values are based on esophageal manometry on patients undergoing induction of anesthesia and cadaver studies of safe amounts of pressure.[100] RSI is widely practiced and approaches a standard of care in patients with a full stomach (i.e., when NPO guidelines have not been observed) and in the setting of bowel obstruction.[101,102] RSI has historically been recommended for patients who are pregnant, starting in the second trimester,[103] but this dogma has been called into question.[104,105] Other clinical situations for which RSI may be considered due to a higher than normal risk for aspiration of gastric contents, include poorly controlled GERD, presence of a nasogastric tube, morbid obesity, and diabetic gastroparesis. RSI is also a useful induction technique when mask ventilation is predicted to be difficult, but intubation is not, such as with an edentulous, bearded patient with an otherwise reassuring airway examination.

Some common variations to RSI have developed from the technique first described in 1970.[106] When succinylcholine is contraindicated or its side effects are undesired, RSI can be accomplished using nondepolarizing NMBDs (rocuronium 1.0 to 1.2 mg/kg or vecuronium 0.3 mg/kg); these doses provide adequate intubating conditions in less than 90 seconds.[107,108] The primary disadvantage with the nondepolarizing NMBDs used to be the prolonged duration of neuromuscular blockade; however, since the introduction of sugammadex these agents are increasingly employed in place of succinylcholine for RSI (also see Chapters 27 and 28). Although traditional RSI calls for induction with a fixed dose of thiopental, the use of other anesthetics such as propofol, etomidate, or ketamine is common. Some advocate for the titration of the chosen anesthetic agent to LOC rather than the delivery of a fixed, predetermined dose.[101]

The application of cricoid pressure is the most controversial aspect of RSI.[101] Opponents point to studies demonstrating that cricoid pressure results in a decrease in lower esophageal sphincter tone, potentially increasing the risk for regurgitation,[109] and to magnetic resonance imaging (MRI) studies showing that cricoid pressure does not, in fact, result in compression of the esophagus, but rather a lateral displacement.[110] Cricoid pressure also worsens laryngeal visualization during DL, potentially lengthening the time to intubation and increasing the risk of pulmonary aspiration, and can result in occlusion of the subglottic airway, resulting in difficulty with tracheal intubation or mask ventilation.[111] On the other hand, advocates argue that properly applied cricoid pressure is effective in reducing the risk of aspiration and that reports of problems are due to incorrect application. The authors of an MRI study of cricoid pressure argue that the position of the esophagus is irrelevant because the effectiveness of cricoid pressure is due to occlusion of the hypopharynx.[112] In general, because of the relatively low risk of application of cricoid pressure, its use is encouraged for RSI unless glottic visualization proves difficult, in which case it can be easily released.

The term *modified RSI* is frequently used, but no standardized definition exists. A survey of anesthesia residents and attending anesthesiologists in the United States showed that the term was most commonly used to refer to the use of mask ventilation in conjunction with cricoid pressure.[113] Indications for this technique include patients at risk for rapid development of hypoxemia (e.g., patients who are obese, pregnant, or critically ill; pediatric patients) in emergent situations during which preoxygenation cannot be satisfactorily completed, or when a longer time to acceptable intubating conditions is required because of the use of standard doses of nondepolarizing NMBDs. Although the effect of PPV with cricoid pressure applied in terms of gastric insufflation of air is not definitively known, gentle PPV (inspiratory pressure <20 cm water [H_2O]) in conjunction with cricoid pressure may be acceptable in these clinical scenarios.[114]

Inhalational Induction of Anesthesia

Another option for the induction of general anesthesia is inhalational induction with volatile anesthetic. This technique is commonly used in pediatric anesthesia to provide a painless, needle-free experience for the child. In adults, an inhalational induction of anesthesia is used when IV access is not available or when the specific advantages of the technique are desirable. Advantages of an inhalational induction of anesthesia are the maintenance of spontaneous ventilation and the potential for gradual changes in the depth of anesthesia and associated respiratory and cardiovascular effects.[22] Inhalational induction of anesthesia has also been used for RSI, with a rapid-onset NMBD administered at LOC[115] (also see Chapter 27).

Sevoflurane is currently the most commonly used volatile anesthetic for inhalational induction because of its lack of pungency and low blood:gas solubility, allowing for a smooth induction of anesthesia that can provide suitable conditions for airway management with or without adjuvant drugs such as NMBDs or opioids.[116] The two principal techniques for sevoflurane induction of anesthesia are a *tidal volume induction*, in which patients are instructed to breathe normally through the face mask, and a *vital capacity induction*, in which patients are instructed to exhale to residual volume and then take a vital capacity breath from the face mask. High delivered concentrations of sevoflurane (8%) are used for vital capacity induction, whereas tidal volume inductions may start with lower sevoflurane concentrations before the concentration is increased. Nitrous oxide (N_2O) can be used with either method to speed induction via the second-gas effect.[117] Both methods are effective and can be used for either LMA placement or tracheal intubation.[116] Deep levels of anesthesia are required to achieve satisfactory intubating conditions when using sevoflurane as a sole induction agent, increasing the risk of adverse effects, such as hypotension. The administration of propofol,[118] rapid-onset opioids,[119,120] NMBDs,[121] and ketamine[122] have all been shown to improve intubating conditions and allow for lower end-tidal concentrations of sevoflurane.

Halothane, which is still used in developing countries, can also be used for inhalational induction of anesthesia.[123] One main disadvantage of halothane is its high blood:gas partition coefficient, which leads to relatively long induction times. It also can produce cardiac dysrhythmias, myocardial depression, and halothane-induced hepatitis. Because of the inability to achieve deep levels of anesthesia with halothane as a result of its side effects, the use of NMBDs, opioids, or both, is often required.[116] The use of desflurane for inhalational induction of anesthesia is limited by its tendency to cause airway irritation, although reports of its use for induction in combination with opioids has been reported.[124,125]

Intravenous Induction Without Neuromuscular Blocking Drugs

IV induction of general anesthesia without the use of NMBDs is commonly used for LMA placement but can be used to achieve satisfactory intubating conditions as well. This technique is useful when the use of succinylcholine is contraindicated and the prolonged recovery time from nondepolarizing NMBDs is undesirable and their reversal not possible (e.g., when sugammadex is not available). Of the commonly available IV anesthetics, propofol is the best suited for induction without muscle relaxation because of its unique ability to suppress airway reflexes and to produce apnea.[126,127] Larger doses are required, however, when propofol is used as a sole anesthetic, increasing the risk of significant hypotension. Improvement of intubating conditions and smaller doses of propofol are possible when rapid-onset opioids (e.g., alfentanil, remifentanil) or IV magnesium are administered.[128,129] Remifentanil is more effective than comparable doses of alfentanil[128]; in combination with propofol 2 mg/kg, remifentanil 4 to 5 µg/kg can reliably provide good-to-excellent intubating conditions.[130] When combined with cricoid pressure and an avoidance of mask ventilation, this induction technique can be used for RSI.[131]

Disadvantages of this technique include a potentially more frequent incidence of difficult intubation,[132] pronounced hemodynamic side effects such as bradycardia and hypotension, and an increased risk for laryngeal morbidity.[86,133] This technique also introduces the risk of opioid-induced muscle rigidity resulting in difficulty with mask ventilation. Although this risk is commonly attributed to chest wall rigidity, studies in intubated patients and patients with tracheostomies have shown that decreases in pulmonary compliance due to chest wall rigidity are not sufficient to explain an inability to mask ventilate after a large dose of an opioid.[134,135] Examination of the vocal cords during induction with opioids has shown that vocal cord closure is the primary cause of difficult ventilation after opioid-induced anesthesia.[136,137] Treatment with small doses of NMBD or topical lidocaine (laryngotracheal anesthesia [LTA]) can be effective in relaxing the vocal cords to allow for mask ventilation and/or intubation.[136]

AIRWAY MANAGEMENT IN AN AWAKE (NON-ANESTHETIZED) PATIENT

As noted in the ASA DAA, a consideration of whether the airway should be secured before or after induction of general anesthesia is one of the basic management choices that should be considered when an airway management plan is being devised.[7] The benefits of awake airway management include the preservation of pharyngeal muscle tone and patency of the upper airway, the maintenance of spontaneous ventilation, an ability to obtain a quick neurologic examination, and a safeguard against aspiration attributable to the preservation of protective airway reflexes.[138] In general, when difficult mask ventilation and difficult intubation are expected, the safest approach to airway management is to secure the airway while the patient remains awake.[7] Other indications for awake airway management include the risk of severe aspiration of gastric contents, facial or airway trauma, severe hemodynamic instability, and unstable cervical spine pathology.[139]

Because of the nature of these indications, tracheal intubation is most often chosen as the goal of awake airway management; however, awake placement of an LMA for diagnostic bronchoscopy has been described. The most useful technique for awake intubation is the flexible scope intubation (FSI),[138] although other techniques have been successfully used, including VAL,[140] optical stylets,[141] lighted stylets,[142] intubating LMAs,[143] and retrograde intubation (RI).[144]

Topical application of local anesthetic to the airway should, in most cases, be the primary anesthetic for awake airway management.[138] Lidocaine is the most commonly used local anesthetic for awake airway management because of its rapid onset, high therapeutic index, and availability in a wide variety of preparations and concentrations.[145,146] Benzocaine and Cetacaine (a topical application spray containing benzocaine, tetracaine, and butamben; Cetylite Industries, Pennsauken, NJ) provide excellent topical anesthesia of the airway, but their use is limited by the risk of methemoglobinemia, which can occur with as little as 1 to 2 seconds of spraying.[147] Topical cocaine is primarily used for anesthesia and vasoconstriction of the nasal mucosa during awake nasotracheal intubation.[148] A mixture of lidocaine 3% and phenylephrine 0.25%, which can be made by combining lidocaine 4% and phenylephrine 1% in a 3:1 ratio, has similar anesthetic and vasoconstrictive properties as topical cocaine and can be used as a substitute.[149]

Topical application of local anesthetic should primarily be focused on the base of the tongue (pressure receptors here act as the afferent component of the gag reflex), the oropharynx, the hypopharynx, and the laryngeal structures; anesthesia of the oral cavity is unnecessary. If a nasotracheal intubation is planned, then the nasal cavity should also be topicalized. Before topical application of local anesthetic to the airway, administration of an anticholinergic agent should be considered to aid in the drying of secretions, which helps improve both the effectiveness of the topical local anesthetic and visualization during laryngoscopy. Glycopyrrolate is usually preferred because it has less vagolytic effects than atropine at doses that inhibit secretions and does not cross the blood-brain barrier. It should be administered as early as possible to maximize its effectiveness.

Direct application of topical cocaine, lidocaine 4% with epinephrine, or lidocaine 3%/phenylephrine 0.25% solution via cotton swabs or cotton pledgets is effective for anesthesia of the nasal mucosa. Oropharyngeal anesthesia can be achieved by the direct application of local anesthetic or by the use of an atomizer or nebulizer. Topical application of local anesthetic to the larynx can be achieved by directed atomization of a local anesthetic or by the *spray-as-you-go* (SAYGO) method, which involves intermittently injecting local anesthetic through the suction port or working channel of a flexible intubation scope (FIS) or optical stylet, as it is advanced toward the trachea.

Topical application of local anesthetic to the airway mucosa using one or more of these methods is often sufficient. If supplemental anesthesia is required, then a variety of nerve blocks may be used. Three of the most useful are the glossopharyngeal nerve block, superior laryngeal nerve block, and translaryngeal block.

The glossopharyngeal nerve supplies sensory innervation to the posterior third of the tongue, vallecula, the anterior surface of the epiglottis, and the posterior and lateral walls of the pharynx, and is the afferent pathway of the gag reflex. To block this nerve, the tongue is displaced medially, forming a gutter (glossogingival groove). A 25-gauge spinal needle is inserted at the base of the anterior tonsillar pillar, just lateral to the base of the tongue, to a depth of 0.5 cm (Fig. 44.9). After negative aspiration for blood or air, 2 mL of 2% lidocaine is injected. The process is then repeated

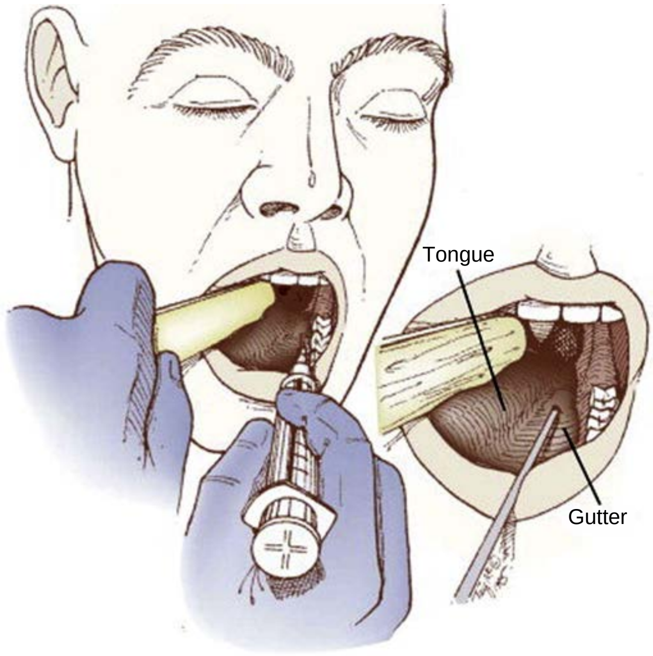

Fig. 44.9 Left glossopharyngeal nerve block. (Reprinted from Artime CA, Sanchez A. Preparation of the patient for awake intubation. From Difficult airway teaching aids, Irvine, University of California, Department of Anesthesia.)

on the contralateral side.[138] The same procedure can be performed noninvasively with cotton-tipped swabs soaked in 4% lidocaine; the swabs are held in place for 5 minutes (Video 44.1).

The superior laryngeal nerve, a branch of the vagus nerve, provides sensory input from the lower pharynx and the upper part of the larynx, including the glottic surface of the epiglottis and the aryepiglottic folds. Blockade of this nerve may be achieved using one of three landmarks (Fig. 44.10). Using either the superior cornu of the hyoid or the superior cornu of the thyroid cartilage, a 25-gauge spinal needle is walked off the cornu anteriorly toward the thyrohyoid ligament. Resistance is felt as the needle is advanced through the ligament, usually at a depth of 1 to 2 cm. After negative aspiration for blood and air, 1.5 to 2 mL of 2% lidocaine is injected and then repeated on the opposite side.[146] The third landmark for the superior laryngeal nerve block is particularly useful in patients who are obese, in whom palpation of the hyoid or the superior cornu of the thyroid cartilage may be difficult or uncomfortable for the patient. In this approach, the needle is inserted 2 cm lateral to the superior notch of the thyroid cartilage and directed in a posterior and cephalad direction to 1 to 1.5 cm depth, where 2 mL of 2% lidocaine is infiltrated and, again, repeated on the contralateral side.[150]

Translaryngeal (or transtracheal) block provides anesthesia of the trachea and vocal cords. This block may be particularly useful in situations where a neurologic examination is needed after intubation; it makes the presence of the ETT in the trachea more comfortable. The CTM is identified, and a 20- to 22-gauge needle attached to 5-mL syringe is directly advanced posteriorly and slightly caudally until air is aspirated, at which point 4 mL of either 2% or 4% lidocaine is quickly injected. This causes the patient to cough,

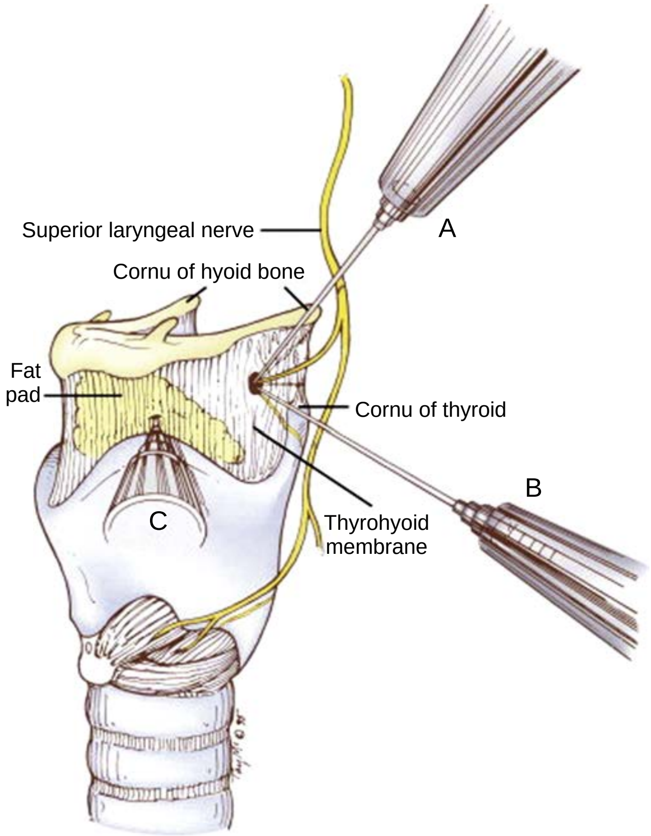

Fig. 44.10 Superior laryngeal nerve block, external approach using as a landmark the greater cornu of the hyoid bone (A), the superior cornu of the thyroid cartilage (B), or the thyroid notch (C). (Reprinted from Artime CA, Sanchez A. Preparation of the patient for awake intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018. From Difficult airway teaching aids, Irvine, University of California, Department of Anesthesia.)

anesthetizing the vocal cords and the trachea. To minimize the risk of trauma, a catheter may first be placed over the needle and the local anesthetic then injected through the catheter (Fig. 44.11 and Video 44.2).[146]

These techniques may be used in various different combinations as long as the maximum dose of local anesthetic is not exceeded. The maximum dose of lidocaine for application to the airway is not well established; different sources suggest total doses in the range of 4 to 9 mg/kg.[146,151,152] Monitoring for signs and symptoms of lidocaine toxicity, including tinnitus, perioral tingling, metallic taste, lightheadedness, dizziness, and sedation is important. Severe lidocaine overdose can cause hypertension, tachycardia, seizures, and cardiovascular collapse.[153]

Depending on the clinical circumstance, IV sedation may facilitate airway management in an awake patient by providing anxiolysis, amnesia, and analgesia. Benzodiazepines, opioids, IV hypnotics, α_2 agonists, and neuroleptics can be used alone or in combination. A summary of common medications used for sedation can be found in Table 44.1. These drugs should be carefully titrated to effect; oversedation can render a patient uncooperative and make awake intubation more difficult. Spontaneous ventilation should always be maintained. Care should be taken in situations with critical airway obstruction since awake muscle tone is sometimes necessary in these patients to maintain airway patency.

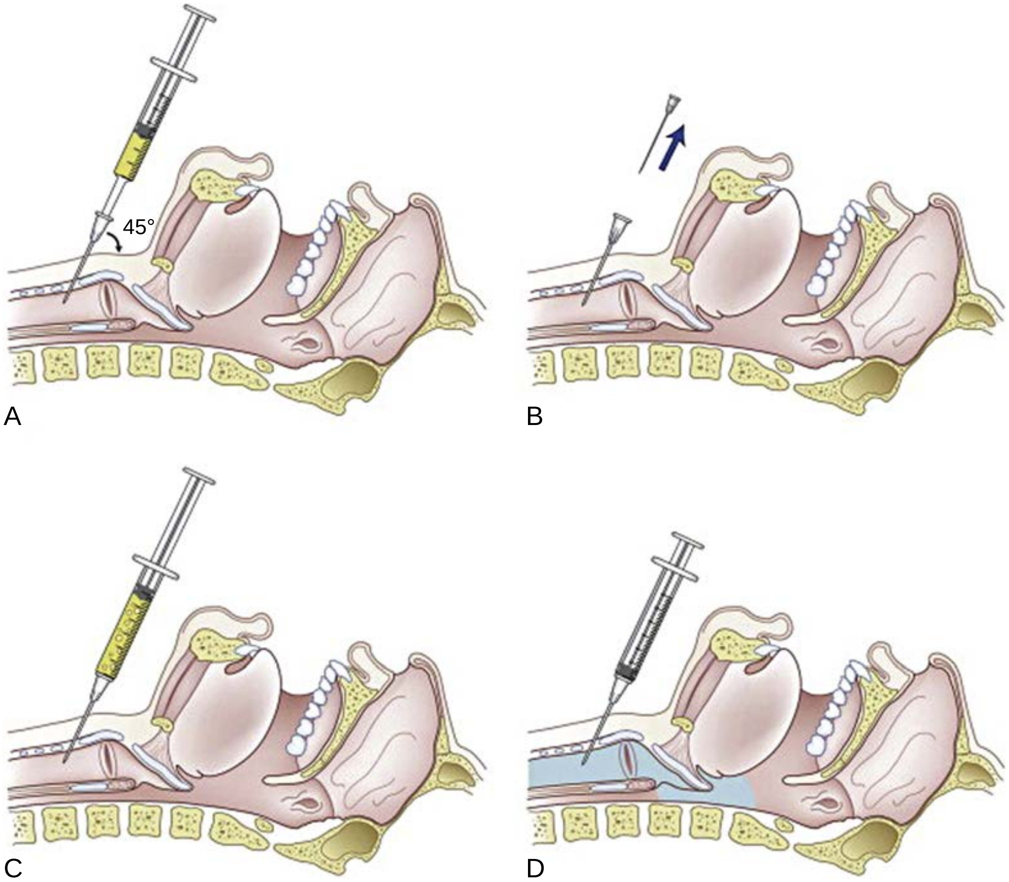

Fig. 44.11 Translaryngeal anesthesia, angiocatheter technique (midsagittal view of the head and neck). (A) The angiocatheter is inserted at the cricothyroid membrane, aimed caudally. An aspiration test is performed to verify the position of the tip of the needle in the tracheal lumen. (B) The needle is removed from the angiocatheter. (C) The syringe containing local anesthetic is attached, and the aspiration test is repeated. (D) Local anesthetic is injected, resulting in coughing and nebulization of the local anesthetic *(shaded blue area)*. (Reprinted from Artime CA, Sanchez A. Preparation of the patient for awake intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018. TABLE 44.1 Sedative Drugs for Awake Airway Management

Drug	Class	Sedative Dose	Notes
Midazolam	Benzodiazepine	1-2 mg IV, repeated prn (0.025-0.1 mg/kg)	Frequently used in combination with fentanyl.
Fentanyl	Opioid	25-200 μg IV (0.5-2 μg/kg)	Usually used in combination with other agents (e.g., midazolam, propofol).
Alfentanil	Opioid	500-1500 μg IV (10-30 μg/kg)	Has a faster onset, shorter duration than fentanyl.
Remifentanil	Opioid	Bolus 0.5 μg/kg IV, followed by an infusion of 0.1 μg/kg/min	Infusion can be subsequently titrated by 0.025-0.05 μg/kg/min in 5-minute intervals to achieve adequate sedation.
Propofol	Hypnotic	0.25 mg/kg IV in intermittent boluses or Continuous IV infusion of 25-75 μg/kg/min, titrated to effect	Can also be used in combination with remifentanil (decrease dose of both drugs).
Ketamine	Hypnotic	0.2-0.8 mg/kg IV	Pretreat with an antisialagogue. Consider administration of midazolam to attenuate undesirable psychologic effects.
Dexmedetomidine	α_2 Agonist	Bolus 1 μg/kg IV over 10 minutes, followed by an infusion of 0.3-0.7 μg/kg/hr	Reduce dose in older adults and in patients with depressed cardiac function.

IV, Intravenous; *prn,* as needed, *pro re nata* (Latin).

Avoiding oversedation is also important in the patient at increased risk for aspiration of gastric contents, because an awake patient can protect his or her own airway if regurgitation should occur.[80]

Mask Ventilation

Mask ventilation is a straightforward, noninvasive technique for airway management that can be used as a primary mode of ventilation for an anesthetic of short duration or as a bridge to establish a more definitive airway. The use of a face mask is common for preoxygenation, inhalational induction of anesthesia, and as a means to provide oxygen and anesthetic gases to both a spontaneous ventilating patient and an anesthetized, apneic patient via PPV. Mask ventilation is not only used to ventilate and oxygenate before conditions for tracheal intubation have been achieved, but it is also a valuable rescue technique when tracheal intubation proves difficult. For this reason, mask ventilation is an important part of the ASA DAA and an essential skill for the anesthesia practitioner.[7]

Mask ventilation is relatively contraindicated when the risk for regurgitation is increased; no protection from pulmonary aspiration of gastric contents exists. Mask ventilation should also be performed with caution in patients with severe facial trauma and in patients in whom head and neck manipulation must be avoided (e.g., those with an unstable cervical spine fracture).

Anesthesia face masks are designed to form a seal around the patient's nose and mouth, allowing for PPV and the administration of anesthetic gases; they should not be confused with oxygen face masks, which are designed only to administer supplemental oxygen. Early anesthesia face masks were reusable and composed of black rubber. These have been almost entirely replaced in clinical use by disposable, clear plastic masks, which are less frightening for patients and have the added benefit of allowing for better visualization of cyanosis or the need for oral suctioning. Face masks are available in various styles and sizes but share a basic design: a main body, seal, and connector. The seal is the portion of the mask that comes in contact with the face, and in clear plastic masks is comprised of a plastic, air-filled, high-volume, low-pressure cushion that conforms to the facial anatomy while minimizing the chance for pressure ischemia; some models have a valve on the cushion to allow changing the volume of the air within. The connector is a standard 22-mm female adapter that allows a connection to a standard anesthesia circuit or a bag-valve device; pediatric masks usually have a 15-mm male adapter that allows the same connections.

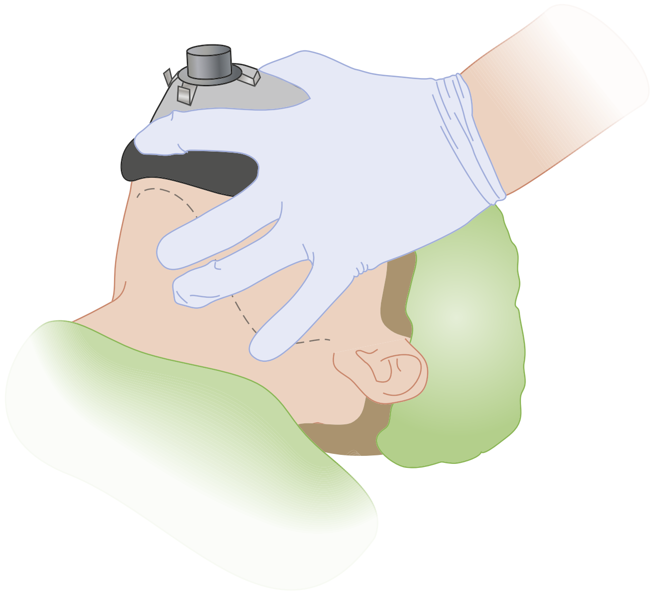

Fig. 44.12 Standard one-handed face-mask ventilation technique. The position of the fifth digit is at the angle of the jaw. (From Matioc AA. The adult ergonomic face mask: historical and theoretical perspectives. *J Clin Anesth*. 2009;21:300–304.)

The technique for mask ventilation is dependent on two key elements: (1) maintenance of a seal between the face mask and the patient's face, and (2) an unobstructed upper airway.[22] The mask is usually held with the left hand, with the thumb and index finger forming a "C" around the collar of the connector, the third and fourth digits on the ramus of the mandible, and the fifth digit on the angle of the mandible (Fig. 44.12). The thumb and index finger are used to produce downward pressure to ensure a tight mask seal, while the remaining digits provide upward displacement of the mandible (jaw thrust) to aid with airway patency. The right hand is free to provide manual ventilation. Ensuring that pressure from the digits is placed on the bony ridge of the mandible and not the soft tissue is important—compression of the submandibular space can cause obstruction of the airway and difficulty with mask ventilation. Many face masks have hooks around the collar for use with mask straps that can facilitate formation of a seal.

The one-handed technique is occasionally ineffective, especially in patients who are obese or edentulous, attributable to the failure to maintain a seal and/or a patent upper airway. In these situations, a two-handed technique can be more successful. Two-handed techniques depend on either an assistant or the use of pressure-control ventilation (PCV) with the anesthesia machine to provide PPV. The use of PCV for mask ventilation results in lower peak airway pressures and reduced inspiratory flow rates when compared with manual ventilation, providing an additional measure of safety against gastric insufflation.[154] In one approach to the two-handed technique, the left hand is positioned as in the one-handed technique and the right hand is placed on the other side of the mask in an identical conformation. A more effective approach involves using the second and third digits to perform a jaw thrust while the mask is held in place with the thumbs (Video 44.3). A study in anesthetized patients showed that this technique improved upper airway patency, compared with the traditional one-handed technique, as measured by greater tidal volumes during PCV.[155] Additional techniques to improve the mask seal in difficult scenarios include leaving dentures in place in edentulous patients and placing an adhesive plastic dressing over facial hair.

Once a seal is established between the face mask and the patient's face, ventilation is achieved by either spontaneous ventilation or PPV. The effectiveness of mask ventilation should be ascertained by observing for chest rise, exhaled tidal volumes, pulse oximetry, and capnography. During controlled ventilation in patients with normal lungs and a

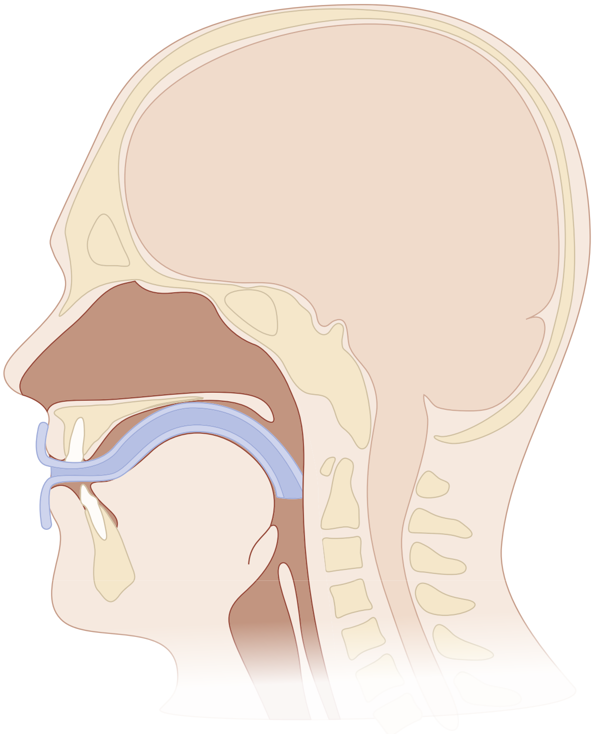

Fig. 44.13 Oropharyngeal airway in place. The airway follows the curvature of the tongue. It pulls the tongue and the epiglottis away from the posterior pharyngeal wall and provides a channel for the passage of air. (Modified from Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 4th ed. Baltimore: Williams & Wilkins; 1999.)

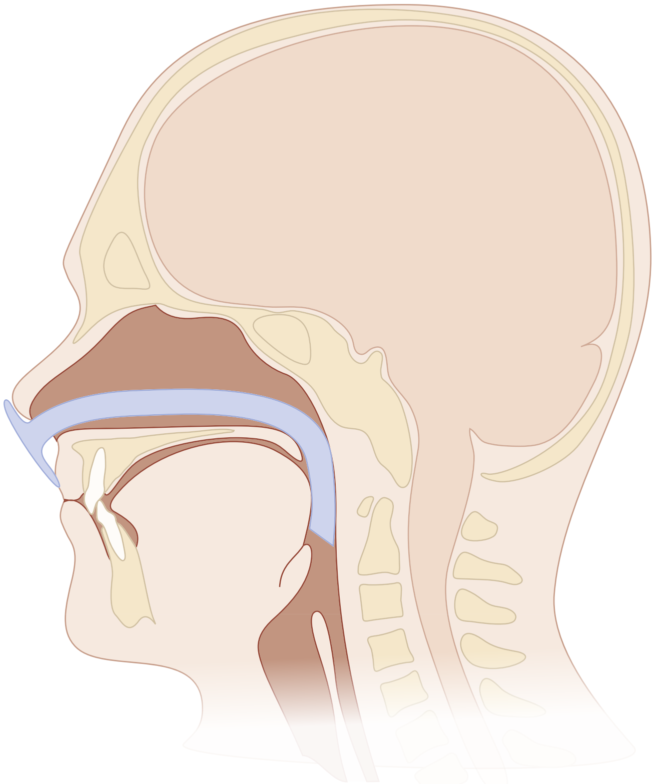

Fig. 44.14 Nasopharyngeal airway in place. The airway passes through the nose and ends at a point just above the epiglottis. (Modified from Dorsch JA, Dorsch SE. *Understanding Anesthesia Equipment*. 4th ed. Baltimore: Williams & Wilkins; 1999.)

patent airway, adequate tidal volumes should be achieved with peak inspiratory pressures less than 20 cm H_2O; higher pressures should be avoided to prevent gastric insufflation.[156] If PPV is inadequate at acceptable inspiratory pressures, then airway patency and pulmonary compliance should be assessed.

Because of a reduction in muscle tone as a result of general anesthesia, tissues fall backward under the influence of gravity in a supine patient and can obstruct the upper airway. Upper airway obstruction most commonly takes place at the level of the soft palate (velopharynx), epiglottis, and tongue.[22,26] To maximize airway patency, mask ventilation can be performed with maximal atlantooccipital extension in combination with the forward displacement of the mandible (jaw thrust) involved in the mask-holding techniques.[157] The addition of cervical flexion to head extension (i.e., placing the patient in the sniffing position) improves pharyngeal patency.[158] If the sniffing position and jaw thrust fail to relieve airway obstruction, then oropharyngeal or nasopharyngeal airways may be used to facilitate airway patency.

Oropharyngeal airways are the most commonly used. They follow the curvature of the tongue, pulling it away from the posterior pharynx (Fig. 44.13). Because they place pressure on the base of the tongue and may come in contact with the epiglottis, oropharyngeal airways can precipitate coughing, retching, or laryngospasm if laryngeal and pharyngeal reflexes are not sufficiently blunted; therefore they are not appropriate for use in conscious patients who have not had local anesthetic applied to the airway. The oropharyngeal airway is sized by measuring from the corner of a patient's mouth to the angle of the jaw or the earlobe. Inappropriately sized oropharyngeal airways can actually worsen airway obstruction; therefore correct size selection is important. Proper placement is accomplished by inserting the oropharyngeal airway with the curvature facing posteriorly and then rotating 180 degrees; alternatively, a tongue depressor can be used to displace the tongue anteriorly as the oropharyngeal airway is inserted with the curvature facing anteriorly. Complications from oropharyngeal airways include lingual nerve palsy and damage to the teeth.[159,160] Nasopharyngeal airways are less stimulating than oropharyngeal airways once in place and thus are more appropriate for conscious patients (Fig. 44.14). They should be well lubricated before insertion and inserted perpendicularly to the longitudinal axis of the body with the bevel facing the nasal septum. To avoid epistaxis, force should never be used during insertion of a nasopharyngeal airway.

Difficult mask ventilation occurs when ventilating via the face mask is not possible because of an inadequate mask seal, excessive gas leak, and/or excessive resistance to the ingress or egress of gas.[7] Predictors for difficult mask ventilation that can be identified during the preoperative airway assessment are listed in Box 44.2.

Supraglottic Airways

The term *supraglottic airway* or *extraglottic airway* refers to a diverse family of medical devices that are blindly inserted into the pharynx to provide a patent conduit for ventilation, BOX 44.2 **Predictors of Difficult Mask Ventilation**

- Obstructive sleep apnea or history of snoring
- Age older than 55 years
- Male gender
- Body mass index of 30 kg/m^2 or greater
- Mallampati classification III or IV
- Presence of a beard
- Edentulousness

oxygenation, and delivery of anesthetic gases without the need for tracheal intubation. SGAs have the advantage of being less invasive than tracheal intubation while providing a more definitive airway than a face mask and can be used for either spontaneous ventilation or PPV. One of the first SGAs, the LMA, was described in 1983 by Dr. Archie Brain and introduced into clinical practice in 1988.[161] Since that time, the LMA has proved to be one of the single most important developments in both routine and difficult airway management and is a pivotal component of the ASA DAA. Various different designs of SGAs are now available and are widely used in current anesthesia practice as a primary airway management device, a rescue airway device, and a conduit for tracheal intubation.

The specific advantages of SGAs include the ease and speed of placement, improved hemodynamic stability, reduced anesthetic requirements, lack of a need for muscle relaxation, and an avoidance of some of the risks of tracheal intubation (e.g., trauma to the teeth and airway structures, sore throat, coughing on emergence, or bronchospasm).[162,163] The primary disadvantages are that SGAs have comparatively smaller seal pressures than ETTs, which can lead to ineffective ventilation when higher airway pressures are required, and they provide no protection from laryngospasm. First-generation SGAs also provide little protection from gastric regurgitation and aspiration, although newer devices have incorporated design elements to minimize this risk.

SGAs have many applications. They are considered the first choice for airway management for diagnostic and minor surgical procedures.[164] No standardized classification system exists for the different designs of SGAs, although several have been proposed. This chapter uses the terminology described by Donald Miller: perilaryngeal sealers; cuffless, anatomically preshaped sealers; and cuffed pharyngeal sealers.[165] Second-generation SGAs are differentiated from first-generation SGAs in that they incorporate features designed to reduce the incidence of aspiration.[166]

LARYNGEAL MASK AIRWAY

LMA Classic

The LMA (LMA North America, San Diego, CA) is the most widely used, well-studied SGA and is the archetype of the perilaryngeal sealer. The original version, the LMA Classic (cLMA), consists of an oval-shaped, silicone mask with an inflatable cuff that sits in the hypopharynx and forms a seal around the periglottic tissues (Fig. 44.15). An airway tube attached to the mask exits the mouth and has a standard 15-mm connector for attachment to an anesthesia circuit or to a bag-valve device. The seal around the laryngeal inlet allows for the delivery of oxygen and inhaled anesthetics during spontaneous ventilation and permits PPV at pressures up to 20 cm H_2O. The cLMA is reusable up to 40 times and is available in a variety of sizes from size 1 (neonate) to size 6 (large adult, >100 kg).

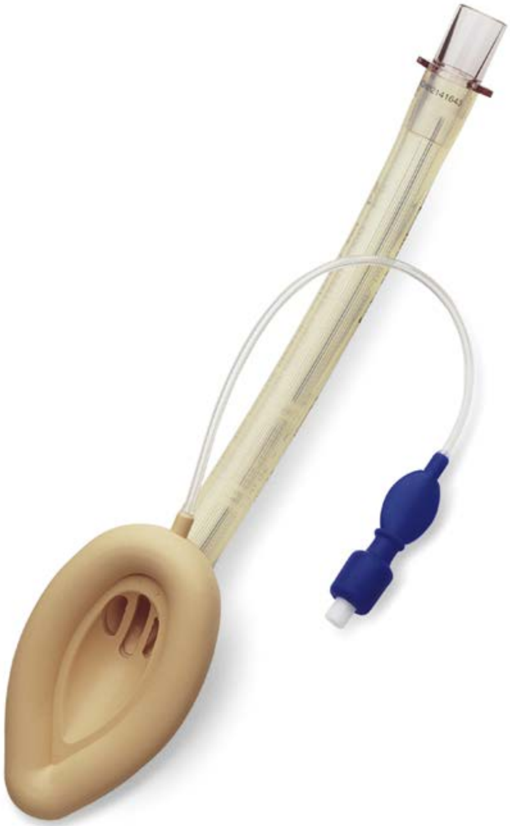

Fig. 44.15 LMA Classic. (Image provided courtesy LMA North America, San Diego, CA.)

The LMA Classic Excel is an updated version that incorporates design features to facilitate tracheal intubation through the device, including an epiglottic-elevating bar, a wider-bore airway tube, and a removable connector. A disposable, single-use version of the cLMA, the LMA Unique, is available with either a polyvinyl chloride (PVC) or silicone cuff and has gained popularity because of its lower cost and maintenance, as well as concerns over the perceived risk of cross-contamination and the transmission of infection with reusable medical devices. The LMA Flexible, available in reusable and single-use models, has a flexible, kink-resistant airway tube that can be positioned away from the surgical field for head and neck procedures.

To achieve a proper fit, the manufacturer of the LMA suggests placing the largest size LMA possible; an airtight seal is achieved more frequently with a size 5 LMA in the average adult man and a size 4 LMA in the average adult woman.[167] Using an undersized LMA can result in overinflation of the cuff to achieve a seal, which can predispose the patient to oropharyngolaryngeal morbidity and nerve damage.[168] Smaller LMA sizes have also been shown to be associated with placement failure.[169] Larger sizes, however, may be

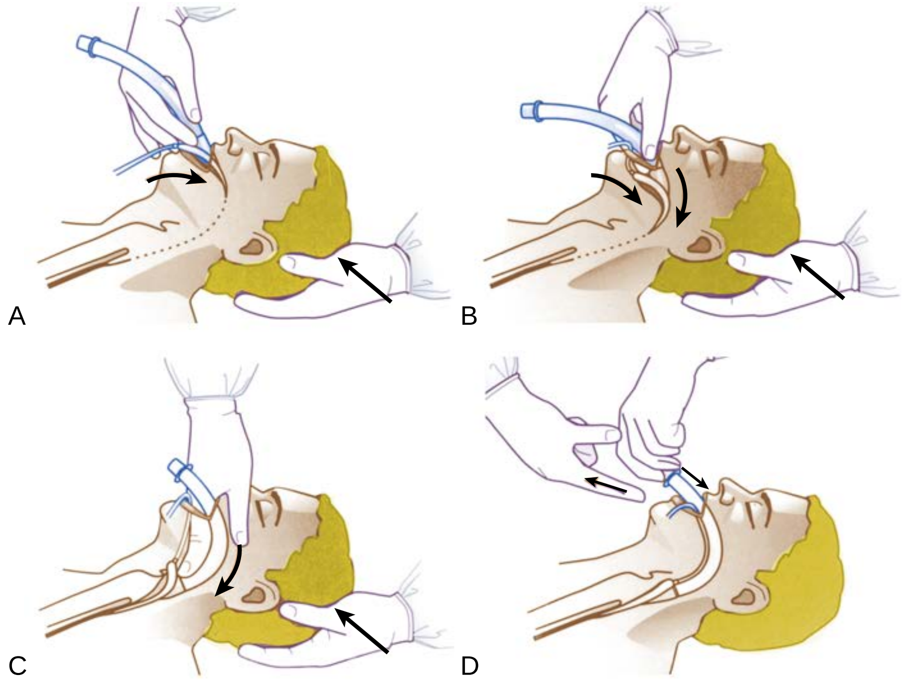

Fig. 44.16 Insertion of a laryngeal mask airway (LMA). (A) The tip of the cuff is pressed upward against the hard palate by the index finger while the middle finger opens the mouth. (B) The LMA is pressed backward in a smooth movement. The nondominant hand is used to extend the head. (C) The LMA is advanced until definite resistance is felt. (D) Before the index finger is removed, the nondominant hand presses down on the LMA to prevent dislodgment during removal of the index finger. The cuff is subsequently inflated. (Courtesy LMA North America, San Diego, CA.)

associated with a more frequent incidence of sore throat; therefore a smaller size may be appropriate when spontaneous ventilation through the LMA is planned.[170]

The manufacturer's instructions for the placement of the cLMA are summarized in Fig. 44.16. Adequate depth of anesthesia for LMA insertion can be achieved with propofol or sevoflurane[171]; short-acting opioids such as fentanyl, alfentanil, and remifentanil may be coadministered to facilitate placement and to decrease the incidence of coughing, gagging, and laryngospasm.[172,173] Before insertion, the LMA cuff should be deflated and the posterior aspect of the mask should be lubricated with a water-based lubricant. Once positioned (see Fig. 44.16), the cuff should be inflated with the minimum effective volume of air, with a target cuff pressure of 40 to 60 cm H_2O.[167] To allow the LMA to position itself correctly, the device should not be secured or attached to the anesthesia circuit until the cuff has been inflated. Confirmation of proper placement is performed by attempting gentle PPV while checking capnography and auscultation and by quantifying the inspiratory pressure at which a leak is audible, which should be 18 to 20 cm H_2O. Once proper positioning is confirmed, a roll of gauze is inserted as a bite block and the LMA is secured in place with tape. Several modifications to the recommended insertion technique have been described, including a *thumb insertion method* by the manufacturer (Video 44.4).[174,175] Cuff pressure should be periodically monitored if N_2O is being used; cuff pressures may increase above the recommended threshold of 60 cm H_2O as a result of diffusion of N_2O into the cuff.

Initial difficulty with ventilation after the placement of an LMA may be due to a down-folded epiglottis. The *up-down maneuver* described by Dr. Brain may help correct this problem; the LMA is withdrawn 2 to 4 cm and reinserted without deflating the cuff. Head extension and LMA repositioning may also improve ineffective ventilation. If these actions do not correct the problem, then a different size may be needed. Insufficient depth of anesthesia, resulting in laryngospasm or bronchospasm, may make ventilation through an LMA impossible; the administration of topical, inhaled, or IV anesthesia can help to correct this. Although not necessary, DL can also facilitate proper LMA placement.

Serious complications from LMA use are relatively rare. More commonly, minor oral, pharyngeal, or laryngeal injury occurs, expressed as complaints of a dry or sore throat.[176] The incidence of sore throat is approximately 10% to 20%,[163,177] and has been linked to higher cuff pressures and larger LMA sizes.[170,178] More serious cases of oropharyngolaryngeal injury have been described, such as trauma to the uvula and pharyngeal necrosis.[179,180] Injury to the lingual, hypoglossal, and recurrent laryngeal nerves has also been reported; these usually spontaneously resolve over a period of weeks to months.[168] Predisposing factors include high cuff pressures (often attributable to the use of N_2O), using too small of an LMA, and nonsupine positions.[168]

LMA ProSeal

The LMA ProSeal (PLMA, LMA North America, San Diego, CA) is a reusable second-generation SGA that incorporates a posterior cuff, improving the perilaryngeal seal and allowing for PPV at pressures up to 30 cm H_2O. It also incorporates a gastric drainage tube that allows for gastric access with an orogastric tube and channels any regurgitated gastric contents away from the airway, effectively isolating the respiratory and gastrointestinal tracts.[181] Additional features include an incorporated bite block and a softer cuff.

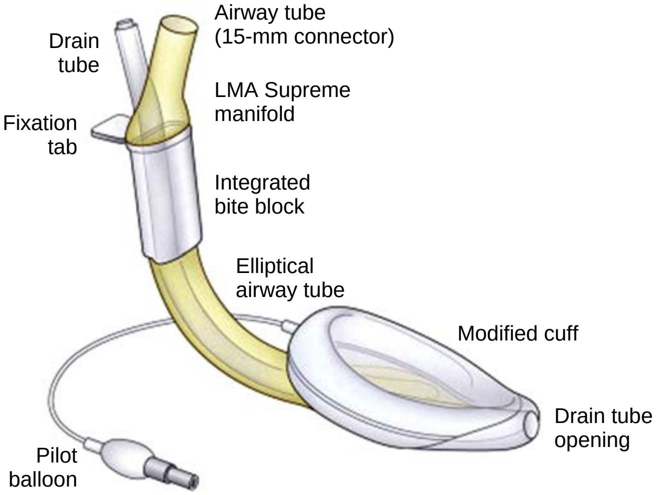

Fig. 44.17 **The LMA Supreme has a modified cuff design, a drainage tube that allows for gastric access, and an integrated bite block.** (From Verghese C, Mena G, Ferson DZ, Brain AIJ. Laryngeal mask airway. In: Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Saunders; 2013.)

The insertion technique is similar to the cLMA but requires deeper anesthetic levels.[181,182] An optional introducer can be used to facilitate insertion. As with the cLMA, cuff pressure should not exceed 60 cm H_2O. Once inserted, assessment of proper placement is accomplished by providing PPV; adequate tidal volumes should be accomplished with reasonable peak inspiratory pressures, leak pressure should be above 20 cm H_2O, and the capnography waveform should appear normal.[22] An additional test to confirm proper placement and separation of the airway and gastrointestinal tract is performed by placing a small layer (<5 mm) of water-based lubricant over the drainage tube orifice; PPV and suprasternal notch palpation should result in a small up-down movement of the gel meniscus. Easy passage of an orogastric tube through the gastric drainage tube confirms proper positioning.

LMA Supreme

The LMA Supreme (SLMA) is a single-use, second-generation SGA based on the PLMA design. Similar to the PLMA, the SLMA has an improved cuff design that produces higher airway leak pressures, a drainage tube that allows for gastric access, and an integrated bite block (Fig. 44.17). A fixation tab allows for determination of proper sizing (the tab should rest 1 to 2.5 cm above the upper lip) and provides an improved perilaryngeal seal when inward pressure is maintained by securing the mask into position by taping cheek to cheek across the fixation tab.

Although not clinically proven, evidence suggests that second-generation SGAs, such as the PLMA and the SLMA, reduce the risk of aspiration of gastric contents. This property, along with the improved airway seal and higher leak pressures, have enabled SGA devices to be used in various applications where the cLMA is potentially unsuitable, such as in nonsupine positions (e.g., lateral, prone),[183] in laparoscopic surgery (e.g., cholecystectomy, gynecologic surgery),[184,185] and in patients who are obese.[186] The successful, routine use of the SLMA in fasted, nonobese patients for cesarean section has also been reported.[187]

NEWER LMA MODELS

The LMA Protector is an all-silicone second-generation SGA with integrated Cuff Pilot Technology, which allows constant cuff pressure monitoring. Color-coded indicator bands alert the clinician to changes in cuff pressure attributable to temperature, N_2O, and movement within the airway, allowing the clinician to maintain the recommended cuff pressure of 40 to 60 cm H_2O. The LMA Protector is designed to channel fluids away from the airway in the unlikely event of regurgitation and allows for gastric suctioning. The airway channel is wide enough to allow intubation with a standard-sized ETT (see Tracheal Intubation Through a Supraglottic Airway Device). The LMA Gastro is a single-use silicone LMA designed for upper gastrointestinal endoscopy procedures, simultaneously protecting the airway and facilitating passage of an endoscope.

OTHER PERILARYNGEAL SEALERS

Over the past 15 years, a multitude of manufacturers have produced SGAs that incorporate the basic perilaryngeal sealing design of the cLMA. Because the term *LMA* is a protected trademark, these devices are referred to as *laryngeal masks* (LMs). Each has its own unique characteristics that may afford it specific advantages over other designs. Although an exhaustive description of every available LM is outside the scope of this chapter, some unique features merit mentioning.

Some design features address the issue of high cuff pressures, which can lead to oropharyngolaryngeal morbidity, nerve palsies, and improper device positioning. The line of LMs manufactured by AES, Inc. (Black Diamond, WA) incorporates a cuff pilot valve (CPV) that allows constant cuff pressure monitoring. The air-Q SP (Cookgas LLC, St. Louis, MO; distributed by Mercury Medical, Clearwater, FL) has a self-pressurizing cuff that uses the positive pressure that ventilates the patient to also pressurize the cuff, obviating the need for an inflation line and eliminating the possibility of cuff overinflation. On exhalation, the mask cuff deflates to the level of positive end-expiratory pressure (PEEP), decreasing the total mucosal pressure over the course of an anesthetic, thereby potentially reducing the incidence of cuff pressure–related complications.

CUFFLESS ANATOMICALLY PRESHAPED SEALERS

Cuffless anatomically preshaped sealers do not have a cuff; rather, they provide an airway seal by their anatomically preshaped design. Advantages include simplicity of insertion and positioning and the lack of a need to inflate a cuff. The first of these devices, the SLIPA (Curveair, London, UK), contains a hollow chamber that can trap regurgitated liquid and prevent aspiration. Other cuffless devices such as the i-gel (Intersurgical Inc., Wokingham, Berkshire, UK) and the Baska Mask (Strathfield, NSW, Australia) can also be included in this classification.

CUFFED PHARYNGEAL SEALERS

Cuffed pharyngeal sealers have an airway with a pharyngeal cuff that seals at the level of the base of the tongue and can be subclassified as to whether they also possess an esophageal sealing cuff.[165] SGAs with only a pharyngeal cuff include the Cobra Perilaryngeal Airway (CobraPLA; Engineered Medical Systems, Indianapolis, IN) and the Tulip Airway (Marshall Medical, Bath, UK); they are not detailed in this chapter. The following devices all have an esophageal sealing cuff.

The esophageal-tracheal combitube (ETC) (Covidien, Mansfield, MA) is a uniquely designed SGA with both a pharyngeal and esophageal sealing cuff and two lumina. The ETC is primarily designed for emergency intubation and is mostly used in the prehospital setting, although it has occasionally been used during general anesthesia as both a primary airway and as a rescue airway device.[188,189] It is inserted blindly through the mouth in a curved, downward motion until the printed ring marks lie between the teeth. Both the proximal, oropharyngeal cuff and the distal esophageal-tracheal cuff are inflated. Greater than 90% of the time, esophageal placement of the device occurs, in which ventilation should be performed via the longer, blue, #1 (esophageal) lumen.[190] This lumen has a closed distal end with eight small perforations located between the two cuffs, which allow oxygenation and ventilation. When the device is placed into the trachea, ventilation should occur via the shorter, clear, #2 (tracheal) lumen, which is open at its distal end. When the ETC is placed in the esophagus, an orogastric tube may be passed through the tracheal lumen to empty the stomach. Use of the ETC as a primary airway is limited by a higher risk of complications, compared with the LMA or tracheal intubation, including hoarseness, dysphagia, and bleeding.[191] Because the oropharyngeal cuff of the ETC contains latex, this device should not be used in latex-sensitive individuals.

The Rüsch EasyTube (Teleflex Medical, Research Triangle Park, NC) is a double-lumen SGA that is similar to the ETC. The primary differences are its nonlatex construction and a proximal lumen that ends just below the oropharyngeal balloon, allowing for the passage of a tube exchanger or FIS. The insertion technique and risks are similar to the ETC; a comparative study showed shorter insertion times with the EasyTube.[192]

The King LT series of SGAs (King Systems Corporation, Noblesville, IN) are similar in design to the ETC and EasyTube, with a ventilation port between the pharyngeal and esophageal cuffs. The King LT and the King LT-D (reusable and disposable, respectively) are single-lumen devices with a tapered distal tip that allows easy passage into the esophagus. The distal (esophageal) portion of the tube is occluded. The King LTS and the disposable King LTS-D, on the other hand, have an open distal tip with a secondary channel to allow suctioning of gastric contents. Although tracheal placement of a King LT device has not be reported, if it should occur, then the device should be removed and reinserted.

Tracheal Intubation

Tracheal intubation is the gold standard for airway management. It establishes a definitive airway, provides maximal protection against the aspiration of gastric contents, and allows for PPV with higher airway pressures than with a face mask or an SGA. Tracheal intubation is usually facilitated by DL; however, a wide variety of alternative intubation devices and techniques have been developed to circumvent the problems encountered when conventional DL is difficult.

In the fasted patient undergoing elective surgery with general anesthesia, an SGA is often suitable. Certain conditions or clinical situations, however, favor tracheal intubation, although the advent of second-generation SGAs has somewhat narrowed this list. Absolute indications for tracheal intubation include patients with a full stomach or who are otherwise at increased risk for aspiration of gastric secretions or blood, patients who are critically ill, patients with significant lung abnormalities (e.g., low lung compliance, high airway resistance, impaired oxygenation), patients requiring lung isolation, patients undergoing otorhinolaryngologic surgery during which an SGA would interfere with surgical access, patients who will likely need postoperative ventilatory support, and patients in whom SGA placement has failed. Other indications for intubation include a surgical requirement for NMBDs, patient positioning that would preclude rapid tracheal intubation (e.g., prone or turned away from the anesthesia provider), a predicted difficult airway, and prolonged procedures.[22]

ENDOTRACHEAL TUBES

The modern, standard ETT is a disposable, single-use, cuffed, plastic tube that is designed to be inserted through the nose or mouth and sit with its distal end in the mid-trachea, providing a patent airway to allow for ventilation of the lungs. A variety of different types of ETTs are available for use in specialized situations. Several features are commonplace among the different styles, however, including a universal 15-mm adapter that allows the attachment of the proximal end to different ventilating circuits and devices; a high-volume, low-pressure cuff; a beveled tip to facilitate passage through the vocal cords; and an additional distal opening in the side wall of the ETT known as a *Murphy eye*, which serves to provide an additional portal for ventilation should the distal end of the lumen become obstructed by either soft tissue or secretions.

Cuffed ETTs are routinely used for tracheal intubation in most patients; cuffless ETTs are used in neonates and infants. The high-volume, low-pressure cuff is inflated with air to provide a seal against the tracheal wall to protect the lungs from pulmonary aspiration and to ensure that the tidal volume delivered ventilates the lungs rather than escapes into the upper airway.[22] A pilot balloon with a one-way valve allows for the inflation of the cuff and an assessment of the cuff pressure. The cuff should be inflated to the minimum volume at which no air leak is present with positive pressure inspiration; the cuff pressure should be less than 25 cm H_2O.[193] Excessive cuff pressure may result in tracheal mucosal injury, vocal cord dysfunction from recurrent laryngeal nerve palsy, and sore throat. Monitoring the cuff pressure with a pressure gauge is recommended. When N_2O is used as part of the anesthetic, cuff pressure should be periodically measured throughout the surgery; N_2O diffusion into the cuff can result in increases in cuff pressure to potentially dangerous levels.

ETT size is normally described in terms of its internal diameter (ID); the relationship of the ID to the external diameter varies between different designs and manufacturers. Selection of the ETT size depends on the reason for placement and patient-specific factors such as gender and airway pathologic conditions. Smaller ETTs result in increased airway resistance and work of breathing, and ETTs with a smaller ID may preclude therapeutic fiberoptic bronchoscopy. Larger ETTs are more likely to be associated with laryngeal or tracheal mucosal trauma and have a higher incidence of sore throat after general anesthesia. Generally, in patients intubated only for the purposes of a general anesthetic, a smaller ETT may be used than on the patient who will remain intubated in the medium to long term as a result of respiratory failure; typically a 7-mm ETT is used for women and a 7.5- or 8-mm ETT is used for men.

A variety of specialized tracheal tubes are available for use in specific clinical situations. Preformed tubes, such as the nasal and oral Ring-Adair-Elwin (RAE) tubes, have a specific contour to maintain a low profile and to avoid surgical interference. Armored (reinforced) tubes have an embedded coil that minimizes kinking of the tube when it is subjected to angulation. Microlaryngeal tubes, which have small IDs with a longer length tube, are useful in laryngeal surgery or for specific applications, such as intubation through a cLMA. The VivaSight ETT (Ambu, Inc., Ballerup, Denmark) has an integrated video camera at the tip, useful during intubation and for confirming ETT position throughout the procedure. Other specialized tubes include laser-resistant tubes and both single- and double-lumen tubes that allow for one-lung ventilation.

ENDOTRACHEAL TUBE INTRODUCERS

ETT introducers are long, slender devices used to assist in guiding an ETT through the glottis. They are particularly useful for performing a blind intubation when the glottic opening cannot be visualized during laryngoscopy.

The original ETT guide was the Eschmann introducer, developed by Venn in 1973.[194] This device, also known as the *gum elastic bougie*, is long enough to allow advancement of an ETT over its distal end after being placed through the vocal cords. It also possesses an anterior angulation at the distal end (coudé tip) to facilitate maneuvering underneath the epiglottis toward the glottic opening, even when the glottic structures are not visualized. A variety of similar introducers with different sizes and features are available; some are hollow to allow for ventilation if the need arises.

Coudé-tip introducers are particularly useful when only a portion of the laryngeal structures, such as only the tip of the epiglottis, can be visualized. Proper placement of the stylet is indicated by the perception of *tracheal clicks* as the coudé tip passes along the tracheal rings and by a *distal hold-up* as it reaches the small bronchi. An ETT is subsequently advanced over the introducer into the correct position (Video 44.5).[195]

OROTRACHEAL VERSUS NASOTRACHEAL INTUBATION

Tracheal intubation can proceed via the orotracheal or nasotracheal route—this decision should be made before deciding which airway management technique will be used. Nasotracheal intubation is generally indicated when the orotracheal route is not possible (e.g., when the mouth opening is severely limited) or when the need for surgical access precludes an orotracheal route. In addition, certain intubation techniques, such as blind intubation, awake intubation, and FSI, are significantly easier when performed through the nose.

When the nasotracheal route is not specifically indicated, however, the orotracheal route is usually preferred for several reasons. The orotracheal route is potentially less traumatic and presents a lower risk of bleeding, it usually allows for the placement of a larger ETT, and it provides for more options in terms of airway management techniques. The major disadvantages include the potential for damage to the teeth and stimulation of the gag reflex during awake intubation, requiring denser airway anesthesia and potentially being less comfortable for the patient. Nasotracheal intubation, on the other hand, bypasses the gag reflex and is usually more easily tolerated by the awake patient. However, the risks of epistaxis, trauma to the nasal turbinates, and submucosal tunneling in the nasopharynx must be taken into account.[138] Nasotracheal intubation is relatively contraindicated in the setting of maxillary or skull base fractures.

DIRECT LARYNGOSCOPY

The most commonly used technique for tracheal intubation is DL, which involves direct visualization of the glottis with the assistance of a laryngoscope. The ETT is inserted through the glottic opening into the trachea under continuous observation.

Preparation and Positioning

Preparation for DL includes proper patient positioning, adequate preoxygenation, and ensuring the availability and proper functioning of all necessary equipment—laryngoscopes, tracheal tubes, tube stylets, an empty syringe for inflating the tracheal tube cuff, a suction apparatus, and the essential equipment for mask ventilation, including an oxygen source. A skilled assistant should be present to help with external laryngeal manipulation and stylet removal, among other tasks. Adequate preparation is of the utmost importance; as with any airway procedure, the first attempt should be the best attempt.

For DL to be successful, a line of sight from the mouth to the larynx must be achieved. The classical model used to describe the anatomic relationships necessary to achieve this was proposed in 1944 by Bannister and Macbeth and involves the alignment of three anatomic axes—oral, pharyngeal, and laryngeal.[196] Positioning the patient in the sniffing position approximates this alignment. Cervical flexion aligns the pharyngeal and laryngeal axes, and maximal head extension at the atlantooccipital joint brings the oral axis closer into alignment (Fig. 44.18). The accuracy of this model has been questioned,[197] and various alternative models to explain the anatomic advantage of the sniffing position have been proposed.[198,199] Regardless of the explanatory model, the evidence in the literature supports the assertion that the sniffing position is the optimal position for DL.[47,200]

Proper positioning in the sniffing position involves approximately 35 degrees of cervical flexion, which is accomplished by a 7- to 9-cm elevation of the head on a firm

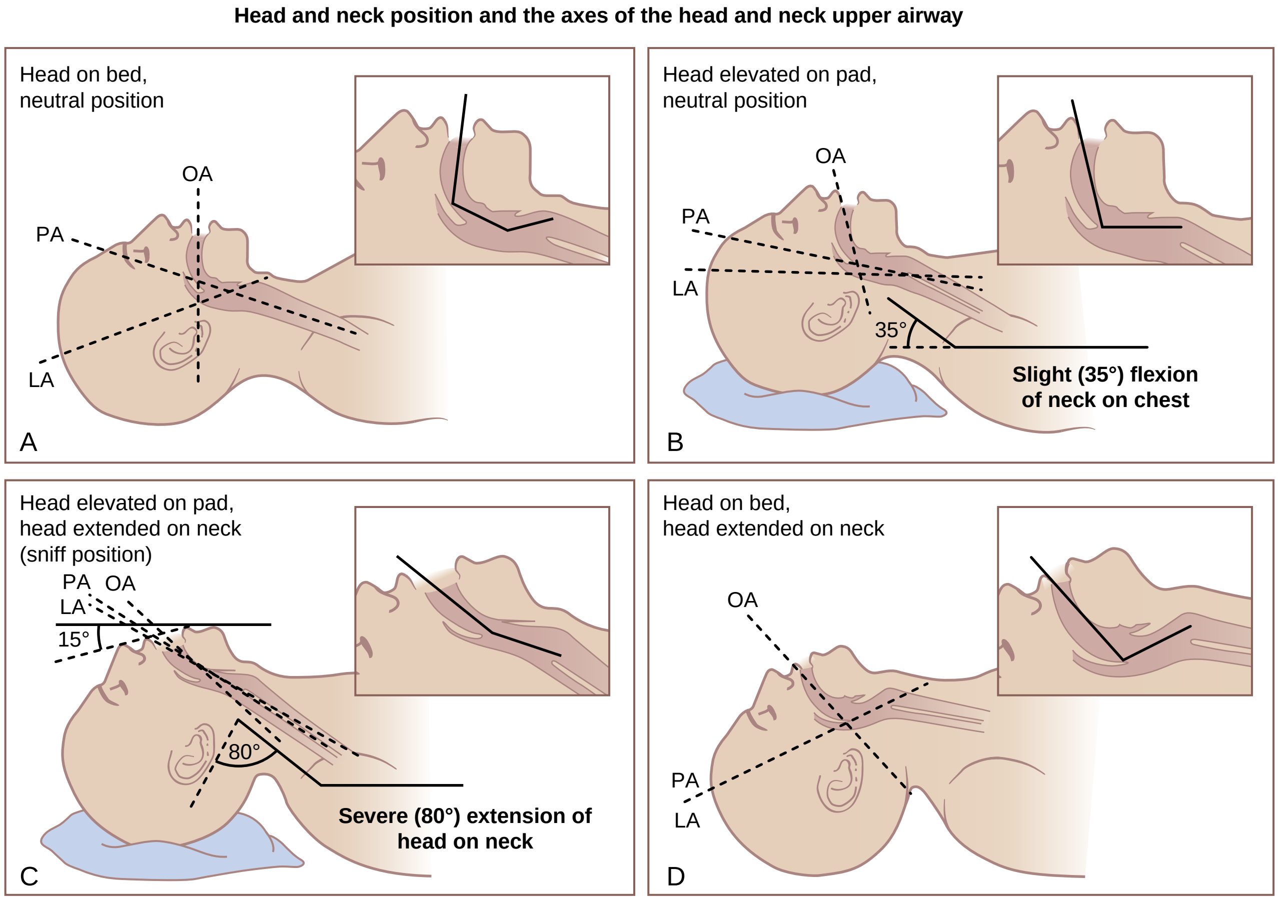

Fig. 44.18 Schematic diagrams show the alignment of the oral axis *(OA)*, pharyngeal axis *(PA)*, and laryngeal axis *(LA)* in four different head positions. Each head position is accompanied by an inset that magnifies the upper airway (oral cavity, pharynx, and larynx) and superimposes *(bold line)* the continuity of these three axes within the upper airway. (A) The head is in the neutral position with a marked degree of nonalignment of the LA, PA, and OA. (B) The head is resting on a large pad that flexes the neck on the chest and aligns the LA with the PA. (C) The head is resting on a pad (which flexes the neck on the chest). Concomitant extension of the head on the neck brings all three axes into alignment (sniffing position). (D) Extension of the head on the neck without concomitant elevation of the head on a pad, which results in nonalignment of the PA and LA with the OA. (From Baker PA, Timmermann A. Laryngoscopic tracheal intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management.* 4th ed. Philadelphia: Elsevier; 2018.)

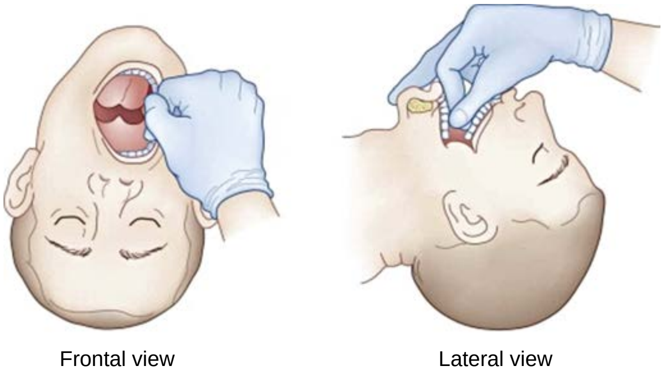
cushion; patients with shorter necks may require less head elevation.[47,201] Patients who are obese often require elevation of the shoulders and upper back to achieve adequate cervical flexion, which can be accomplished by placing the patient in the *ramped* position using either a specialized device, such as the Troop Elevation Pillow (Mercury Medical, Clearwater, FL), or folded blankets. Confirming horizontal alignment of the external auditory meatus with the sternal notch is useful for ensuring optimal head elevation in both obese and nonobese patients.[202] Adequate cervical flexion also facilitates maximal atlantooccipital extension, which provides optimal alignment of the oral and pharyngeal axes (the primary determinant for quality of laryngeal view) and enhanced mouth opening.[203]

Technique

The laryngoscope is a handheld instrument consisting of a blade attached to a handle containing a light source. Most are reusable and made of steel, although disposable, plastic versions are available. The curved blade and the straight blade are the two basic types of laryngoscope blades available for DL; multiple variations of both styles exist. The Macintosh is the most commonly used curved blade, whereas the Miller is the most commonly used straight blade. Both are designed to be held in the left hand, and both have a flange on the left side that is used to retract the tongue laterally. Each type of blade has its benefits and drawbacks and is associated with its own technique for use.

The technique for laryngoscopy consists of the opening of the mouth, inserting the laryngoscope blade, positioning of the laryngoscope blade tip, applying a lifting force exposing the glottis, and inserting a tracheal tube through the vocal cords into the trachea. Mouth opening is best achieved using the *scissors* technique; the right thumb pushes caudally on the right lower molars while the index or third finger of the right hand pushes on the right upper molars in the opposite direction (Fig. 44.19).

The decision of whether to use a Macintosh or a Miller blade is multifactorial; however, the personal preferences and experience of the laryngoscopist is a significant consideration. In general, the Macintosh is most commonly used for adults, whereas the straight blades are typically used in pediatric patients.[204] Curved blades provide greater room for passage of an ETT through the oropharynx, attributable to their larger flange, and are generally considered less likely to cause dental damage.[205] Straight blades are preferred in patients with a short thyromental distance or prominent incisors, and usually provide a better view of the glottis in patients with a long, floppy epiglottis. Often, when one style of laryngoscope does not provide an adequate view of the glottis, the other may be more effective. For most adults, a Macintosh size 3 or a Miller size 2 blade is usually the proper size; in larger patients or patients with a very long thyromental distance, a larger blade may be more appropriate.



Frontal view
Lateral view

Fig. 44.19 The scissors technique for mouth opening. The thumb of the right hand is pressed on the right lower molars in a caudad direction while the index or third finger of the right hand presses on the right upper molars in a cephalad direction. (From Baker PA, Timmermann A. Laryngoscopic tracheal intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

The Macintosh blade is inserted in the right side of the mouth, and the flange is used to sweep the tongue to the left. Once the laryngoscope has been inserted in the mouth, the right hand can be used to ensure that the upper lip is not impinged between the laryngoscope and the upper incisors. The blade is advanced along the base of the tongue until the epiglottis is visualized; the tip of the blade is then advanced further and positioned in the vallecula. A force oriented at a 45-degree angle up and away from the laryngoscopist indirectly lifts the epiglottis by placing tension on the hyoepiglottic ligament, exposing the glottic structures (Fig. 44.20). The tip of the blade should not be lifted by using the laryngoscope as a lever, rocking back on the upper incisors, which can damage the teeth and provides an inferior view of the glottis. A properly oriented vector of force is achieved by using the anterior deltoid and triceps, not by radial flexion of the wrist. Once a complete view of the glottis is achieved, the ETT is grasped similar to a pencil with the right hand and guided through the vocal cords into the trachea. Passage of the ETT may be facilitated by an anterior angulation of the tip, which can be accomplished by shaping the ETT with a malleable stylet into a *hockey stick* shape, with approximately a 60-degree angle formed 4 to 5 cm from the distal end, or by accentuating the natural anterior curvature of the ETT by inserting the tip into the 15-mm connector, forming a circle, for several minutes before performing DL.

Fig. 44.20 Laryngoscopy technique with a Macintosh (curved) blade. (A) The laryngoscope blade is inserted into the right side of the mouth, sweeping the tongue to the left of the flange. (B) The blade is advanced toward the midline of the base of the tongue by rotating the wrist so that the laryngoscope handle becomes more vertical *(arrows)*. (C) The laryngoscope is lifted at a 45-degree angle *(arrow)* as the tip of the blade is placed in the vallecula. (D) Continued lifting of the laryngoscope handle at a 45-degree angle results in exposure of the laryngeal aperture. The epiglottis (1), vocal cords (2), cuneiform cartilage (3), and corniculate cartilage (4) are identified. (From Baker PA, Timmermann A. Laryngoscopic tracheal intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

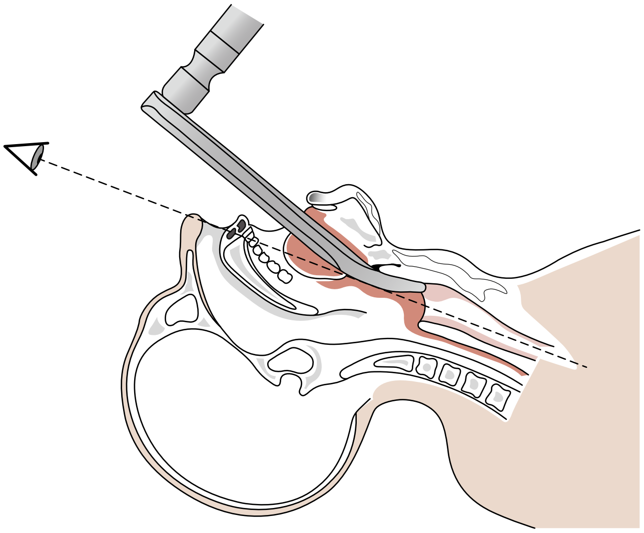

Fig. 44.21 Paraglossal laryngoscopy technique with a Miller (straight) blade. The blade is at the right side of the tongue. The line of sight over the molars is achieved by rotating the head to the left and moving the heel of the laryngoscope to the right. The tip of the blade is placed beneath the epiglottis and a 45-degree lifting force applied to expose the glottic aperture. (From Baker PA, Timmermann A. Laryngoscopic tracheal intubation. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

The Miller laryngoscope blade is inserted using the paraglossal technique described by Henderson.[22] This method provides maximal tongue control and avoids contact of the laryngoscope with the maxillary incisors. The laryngoscope is inserted lateral to the tongue and carefully advanced along the paraglossal gutter between the tongue and tonsil. Application of continued moderate lifting force to the laryngoscope handle helps maintain lateral displacement of the tongue and reduces contact with the maxillary teeth. As the laryngoscope is advanced, the epiglottis comes into view and the tip of the laryngoscope is passed posterior to the epiglottis. The optimal position of the tip of the straight laryngoscope is in the midline of the posterior surface of the epiglottis, close to the anterior commissure of the vocal cords (Fig. 44.21).[22] This position achieves good control of the epiglottis and facilitates the passage of the tracheal tube. The direction of force applied to the handle is the same as when using the Macintosh blade.

The use of external laryngeal manipulation can improve the laryngeal view. Backward, upward, rightward pressure (the BURP maneuver) on the thyroid cartilage is most commonly used. Optimal external laryngeal manipulation (OELM) is achieved when the laryngoscopist uses his or her right hand to guide the position and pressure is exerted by an assistant's hand on the larynx (Fig. 44.22).

Difficulty with tracheal intubation by DL is primarily a function of an inadequate view of the glottis. Predictors for difficult laryngoscopy that can be identified during the preoperative airway assessment are listed in Box 44.3. Cormack and Lehane developed a grading scale in 1984 to describe laryngoscopic views.[206] The grades range from I to IV, beginning with grade I (the best view), in which the epiglottis and vocal cords are in complete view, and culminating with grade IV (the most difficult view), in which the epiglottis or larynx is not visualized (Fig. 44.23). A modified classification scheme with five different grades based on the Cormack-Lehane scoring system is described by Yentis, who proposed that grade II be differentiated into IIA (partial view of the glottis) and IIB (arytenoids or posterior vocal cords only are visible).[207] Intubation is rarely difficult when a grade I or IIA view is achieved; grades IIB and III are associated with a significantly higher incidence of failed intubation. A grade IV laryngoscopic view requires an alternate method of intubation. An alternate method of rating laryngoscopic view is the percentage of glottic opening (POGO) scale, which is determined by the percentage of the vocal cords from the anterior commissure to the arytenoid notch that can be visualized during laryngoscopy. This scale has been shown to have a higher interobserver reliability than the Cormack-Lehane scoring system and is potentially more useful for research studies in direct and indirect laryngoscopy.[208]

When the laryngeal view is inadequate, the laryngoscopist should verify that the patient is in an optimal position, that OELM is being provided, and that the laryngoscope has not been inserted too deeply. Whether a larger laryngoscope or an alternate style of blade would be beneficial should be

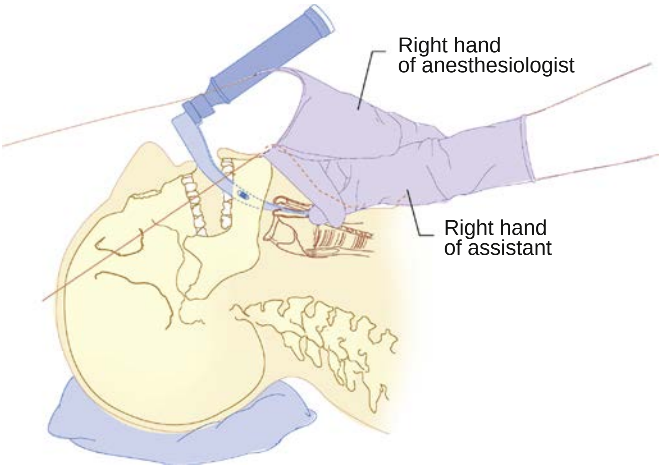

Fig. 44.22 Optimal external laryngeal manipulation. The laryngoscopist guides the position, and pressure is exerted by the assistant's hand on the larynx to maximize the view of the vocal cords. The left hand of the laryngoscopist, which holds the laryngoscope handle, is omitted. (From Henderson J. Airway management. In: Miller RJ, ed. *Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2009.)

BOX 44.3 **Predictors of Difficult Laryngoscopy**

- Long upper incisors
- Prominent overbite
- Inability to protrude mandible
- Small mouth opening
- Mallampati classification III or IV
- High, arched palate
- Short thyromental distance
- Short, thick neck
- Limited cervical mobility

Modified from Apfelbaum JL, Hagberg CA, Caplan RA, et al. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2013;118:251–270.

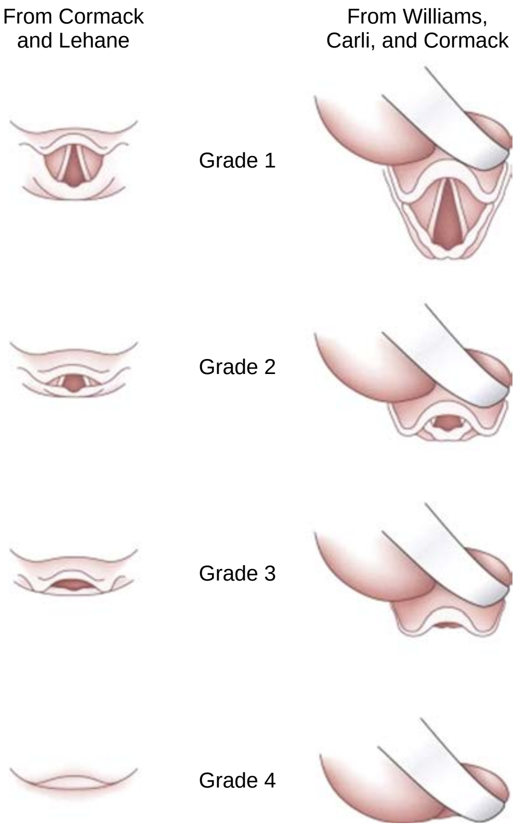

Fig. 44.23 **The Cormack-Lehane grading system for laryngoscopic view. Grade 1 is visualization of the entire laryngeal aperture; grade 2 is visualization of only the posterior portion of the laryngeal aperture; grade 3 is visualization of only the epiglottis; and grade 4 is no visualization of the epiglottis or larynx.** (Modified from Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia.* 1984;39:1105; and Williams KN, Carli F, Cormack RS. Unexpected difficult laryngoscopy: a prospective survey in routine general surgery. *Br J Anaesth*. 1991;66:38.)

considered. When the ETT cannot be passed into the trachea under direct visualization, the options include the following: (1) attempts at blind passage of the ETT, which risks laryngeal trauma, bleeding, and airway obstruction; (2) the use of an ETT introducer; and (3) alternative approaches to intubation as per the ASA DAA.

When the glottic view is adequate, the ETT should be inserted into the right corner of the mouth and advanced such that it intercepts the long axis of the laryngoscope blade at the glottis, rather than inserted midline and parallel to the long axis of the laryngoscope blade, ensuring that the view of the glottis is not obscured. The tip of the ETT is passed through the glottic inlet and advanced until the proximal portion of the cuff is approximately 2 cm past the vocal cords. If a stylet is being used, then the stylet should be removed when the tip of the ETT is at the level of the vocal cords while the ETT is firmly held stationary; this technique helps limit trauma to the tracheal mucosa from the semirigid stylet.

Nasotracheal Intubation Technique

Before nasotracheal intubation, the more patent nostril should be selected. This selection can be accomplished by separately occluding each nostril and having the patient inhale—the patient will usually be able to inhale more effectively through one of the nares. To reduce the risk of epistaxis, a nasal mucosal vasoconstrictor (e.g., cocaine, phenylephrine, oxymetazoline) should be administered. The nasal ETT should be lubricated and inserted into the naris with the bevel facing away from the midline, which decreases the risk of avulsion of a turbinate. Cephalad traction should be applied as the ETT is advanced through the nasal passage to ensure a trajectory along the floor of the nose, beneath the inferior turbinate.

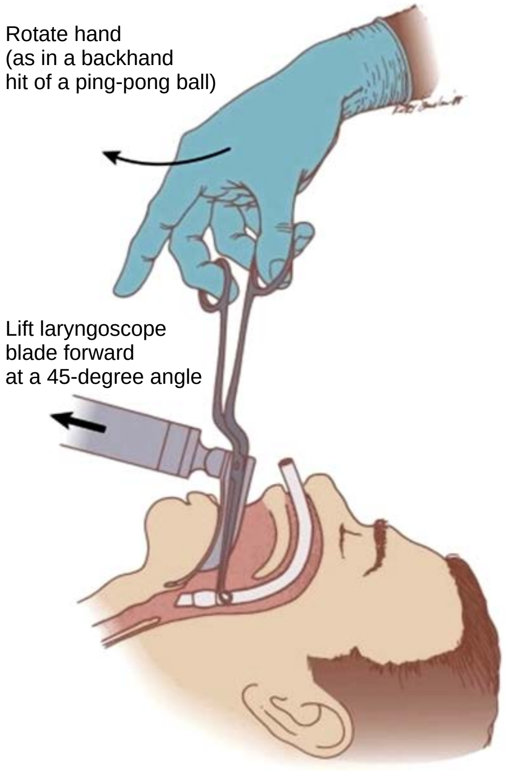

Fig. 44.24 **Guiding a nasal endotracheal tube into the larynx with Magill forceps.** (From Berry JM, Harvey S. Laryngoscopic orotracheal and nasotracheal intubation. In: Hagberg CA, ed. *Benumof and Hagberg's Airway Management*. 3rd ed. Philadelphia: Saunders; 2013, p. 357.)

Once the ETT enters the oropharynx (typically at a depth of 14 to 16 cm), standard DL is performed. The ETT can be guided into the laryngeal inlet by repositioning the head as the ETT is advanced or with the aid of Magill forceps (Fig. 44.24). Care should be taken to grasp the ETT proximal to the cuff to prevent cuff damage. Other techniques for nasotracheal intubation include blind nasal intubation, VAL, and FSI.

Confirmation of Endotracheal Tube Placement

Once the ETT is in place, the laryngoscope is removed from the mouth, the ETT cuff is appropriately inflated, and the patient is manually ventilated while the ETT is manually held in place. Immediate verification of endotracheal placement of the ETT is necessary; esophageal or endobronchial intubation is a significant source of avoidable anesthetic-related morbidity and mortality. Endotracheal placement can be determined by confirmation of chest rise, visible condensation in the ETT, equal breath sounds bilaterally over the chest wall, lack of breath sounds over the epigastrium, large exhaled tidal volumes, and appropriate compliance of

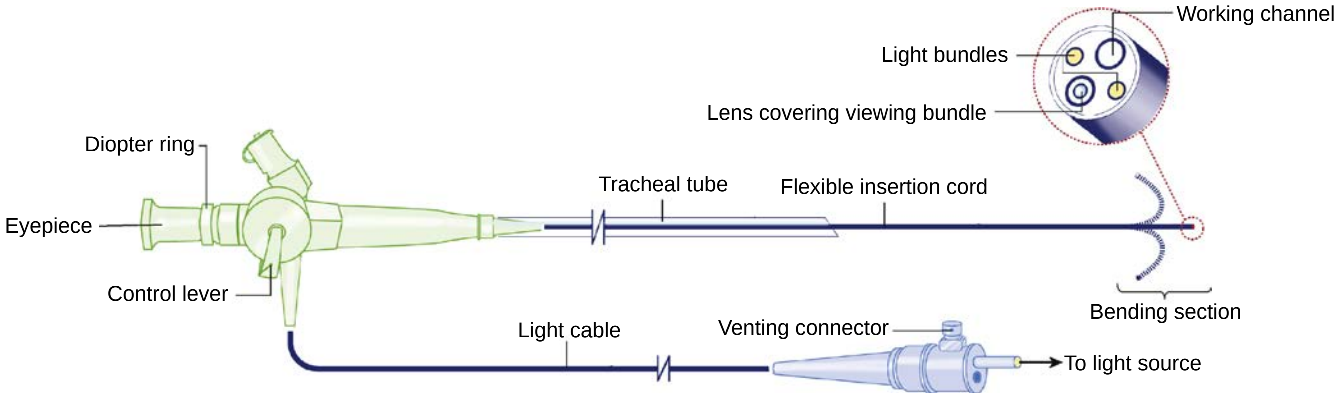

Fig. 44.25 **Flexible fiberoptic bronchoscope.** (From Henderson J. Airway management. In: Miller RJ, ed. *Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2009.)

the reservoir bag during manual ventilation.[209] The most important and objective indicator of tracheal intubation, however, is the presence of a normal capnogram (carbon dioxide [CO_2] waveform) for the presence of at least three breaths. Severe bronchospasm, equipment malfunction, cardiac arrest, or hemodynamic collapse may prevent the appearance of a capnogram tracing despite proper ETT placement. If doubt remains, then flexible bronchoscopy, although not routinely used, is very reliable at confirming ETT placement.

Hypoxemia, increased airway pressures, asymmetric chest expansion, and the absence of breath sounds over one lung, generally the left, are indicative of endobronchial intubation; pneumothorax can also produce this picture. Flexible bronchoscopy or chest radiography can be used if the clinical picture is unclear.

Securing the Endotracheal Tube

Once the proper depth of the ETT has been determined, the tube should be secured in place to prevent movement and inadvertent endobronchial intubation or extubation. The most common method is to tape the ETT to the skin of the face. Because it is less mobile, the skin of the maxilla is preferred. When tape cannot be used, such as in the case of a severe tape allergy, extensive facial burns, or epidermolysis bullosa, a surgical mask may be tied around the back of the head to secure the ETT. Other methods that may be used for intraoral or facial surgery include wire fixation to a tooth or suturing the ETT to the skin of the cheek.

INDIRECT LARYNGOSCOPY

Conventional DL requires wide mouth opening, cervical flexion, and atlantooccipital extension to create a direct line of vision from the mouth to the larynx. In certain conditions, this positioning is impossible or contraindicated. Other times, attributable to anatomic variations in the airway (e.g., redundant soft tissue, protruding incisors, anterior larynx), DL cannot be achieved, despite optimal positioning and technique. Indirect laryngoscopy entails the indirect visualization of the glottis by way of optical aids, such as fiberoptic bundles, video cameras, mirrors, prisms, or lenses. Various different devices that use indirect laryngoscopy are available, including FISs, video laryngoscopes (VLs), and intubating optical stylets. They are indispensable tools for the management of the known or predicted difficult airway. Because no direct line of sight is needed, visualization of the larynx can occur without tissue distortion; consequently, these techniques can be readily used with topical anesthesia in an awake patient.[22]

Flexible Intubation Scopes

The FIS is the most widely used, versatile, indirect laryngoscopy device. Since the first use of fiberoptics for airway management in 1967, FISs, including the flexible fiberoptic bronchoscope (FOB), have become invaluable tools for tracheal intubation in both awake and anesthetized patients. There are various clinical scenarios within which FSI provides a superior technique for airway management, as compared with DL or alternative airway devices. FSI of the awake and cooperative, spontaneously ventilating patient is considered the *gold standard* for the management of the difficult airway.[195]

The standard FOB (Fig. 44.25) consists of thousands of flexible glass fibers approximately 8 to 10 μm in diameter that are capable of transmitting reflected light along their length. Light is transmitted from an external light source to the distal end of the FOB; the light reflecting off the object to be viewed is transmitted back along the length of the FOB to an eyepiece or video camera at the proximal end of the scope. In recent years, FOBs have been replaced by modern FISs that use video chip and light-emitting diode (LED) technology instead of fiberoptics.

Indications for FSI essentially include any indication for tracheal intubation. However, FSI may be the airway management technique of choice in any one of the following clinical scenarios[195]:

- Known or anticipated difficult airway (i.e., cannot intubate or cannot ventilate [CICV])
- Contraindication to extension of the neck (e.g., unstable cervical fracture, severe cervical stenosis, vertebral artery insufficiency, Chiari malformation)
- Increased risk of dental damage (e.g., poor dentition, fragile dental work)
- Limited mouth opening (e.g., TMJ disease, mandibular-maxillary fixation, severe facial burns)

No specific contraindications exist for FSI; however, in certain clinical situations, successful FSI is unlikely. Severe airway bleeding can obscure anatomic landmarks and soil the tip of the FIS with blood, making visualization of the larynx extremely difficult. Obstruction or severe stenosis of the airway, resulting in the inability to pass an FIS, can also make FSI impossible.

FSI provides several advantages over DL[195]:

- Allows for a more complete visual examination of the airway before intubation.
- Provides confirmation of tube placement, avoiding esophageal and endobronchial intubation.
- Eliminates the need for three-axis alignment; therefore FSI is among the techniques least likely to result in cervical spine movement.
- Is well-tolerated in awake patients; results in less tachycardia and hypertension.
- Has less of a potential for airway and dental trauma.
- Can be performed in multiple positions.

FSI can be performed in the awake or anesthetized patient. Indications for an awake FSI are generally those situations in which ventilation via a mask is anticipated to be difficult, when a postintubation neurologic examination is needed, or when induction of general anesthesia could cause adverse hemodynamic or respiratory consequences. The major technical disadvantage to performing FSI under general anesthesia is the loss of pharyngeal muscle tone, which can lead to upper airway collapse and difficult fiberoptic laryngoscopy.[195]

Before its use, the anesthesia practitioner or skilled assistant must ensure that the FIS, light source, and video monitor are in proper working condition and that all components have been fully prepared for use. This preparation includes focusing the image if using a FOB, ensuring proper view orientation if using a video camera, lubricating the distal third of the flexible insertion cord, applying antifogging solution to the tip of the scope, and connecting a suction line or oxygen source to the suction port. The ETT should be prepared by placing it in a warm water bath, which softens the plastic, easing passage into the trachea and minimizing airway trauma.

FSI is usually performed in the supine or sitting (i.e., beach-chair) position, although emergency FSI in the lateral decubitus or even prone position has also been described.[210] When performing FSI in the supine position, the anesthesia provider stands at the head of the patient. Advantages to this position are that the laryngeal view through the FIS is in the same orientation as during DL, and the patient and physician are already in the optimal position to perform mask ventilation or other airway maneuvers, if necessary. When performing FSI with the patient in the sitting or beach-chair position, the practitioner should stand facing the patient at the patient's side. This position may be the position of choice in awake FSI because of improved ventilation and greater patient comfort. In addition, the sitting position optimizes airway anatomy and prevents airway collapse in patients who are obese, in patients with obstructive sleep apnea, and in patients with anterior extrinsic airway obstruction.[211]

Before FSI, unless contraindicated, an anti-sialagogue, such as glycopyrrolate 0.2-0.4 mg IV, may be administered to dry airway secretions. Both the orotracheal and nasotracheal routes can be used for FSI. While weighing the advantages and disadvantages, the clinician should determine which approach is best-suited for the clinical situation. Whichever route is chosen, however, essentially two steps to FSI must be taken[195]:

1. Indirect laryngoscopy and endoscopy are performed, obtaining a view of the glottis with the FIS and maneuvering the FIS through the vocal cords into the trachea.
2. The ETT is advanced over the FIS into its proper position in the trachea, and the FIS is removed.

When performing orotracheal FSI, navigating the FIS around the base of the tongue to achieve a satisfactory view of the larynx is one of the major challenges. The FIS has a tendency to stray off the midline, and, frequently, little to no airspace is found between the tongue and the palate through which to navigate the FIS. To mitigate this issue, several devices or techniques can be used. Specialized intubating oral airways can be used to protect the FIS from damage by biting, to prevent the tongue from falling back into the pharynx and obstructing the airspace, and to keep the FIS midline while it is guided to the larynx. Several types of intubating oral airways are available, each with unique design differences, and include the Ovassapian, Berman, and Williams airways. A disadvantage of these devices is that they place pressure on the base of the tongue, potentially causing gagging in awake patients. In both awake patients and those under general anesthesia, gentle traction on the tongue anteriorly is helpful in preventing the tongue from falling back into the pharynx if an intubating airway is not used. This traction can be easily accomplished by hand with the help of 4- × 4-inch gauze pads for traction or with Magill forceps. Care should be taken to not injure the tongue on the bottom teeth. As previously described, LMAs and intubating LMAs can also be used as conduits for oral FSI. Obtaining a laryngeal view during nasal FSI is often easier, as compared with the oral approach, as a result of the fact that the FIS stays midline and the tip of the FIS is usually directed at the glottis as it enters the oropharynx.

Once the FIS has been successfully positioned in the oropharynx, the epiglottis and vocal cords can usually be visualized with a slight anterior deflection of the tip of the FIS. The FIS is aimed toward the anterior commissure of the vocal cords and posteriorly flexed to enter into the trachea. The trachea is easily identifiable by the presence of the cartilaginous tracheal rings. The FIS is advanced distally until a point just above the carina, and the ETT is advanced over the FIS while continually visualizing the trachea through the FIS, providing confirmation that the FIS and ETT have not been accidentally dislodged into the oropharynx or esophagus (Video 44.6). Frequently, especially with orotracheal intubation, resistance is met as the tip of ETT reaches the glottic inlet. Often, this resistance has been shown to be attributable to the bevel of the ETT impinging on the right arytenoid.[212] A slight withdrawal of the ETT and a counterclockwise 90-degree turn, orienting the bevel posteriorly, usually resolves this issue. For nasotracheal intubation, a clockwise 90-degree turn, ensuring that the bevel is oriented anteriorly, can prevent the tip of the ETT from impinging on the epiglottis. Alternatively, the Parker Flex-Tip ETT (Parker Medical, Englewood, CO), which has a bull-nosed tip directed toward the center of the distal lumen, can be used. This ETT has been shown to have a high first-pass success rate when being advanced over an FIS.[213]

After successful passage of the ETT, proper depth (2 to 3 cm from the carina) is confirmed during the withdrawal of the FIS. On rare occasions, the FIS may prove difficult to remove from the ETT, which may be attributable to the FIS having passed through the Murphy eye rather than the distal lumen or a result of inadequate lubrication of the FIS. In these situations, forceful removal may damage the device; therefore the FIS and ETT should be removed as a unit and the procedure repeated.

Rigid Indirect Laryngoscopes

The first indirect laryngoscopes for intubation were based on modifications of the standard direct laryngoscope and used mirrors or prisms to project an image at an angle from the horizontal, facilitating visualization of the larynx. Modern indirect laryngoscopes based on the direct laryngoscope design that use optical lenses to project a refracted image of the glottis include the Viewmax (Rüsch, Duluth, GA) and the TruView EVO2 (Truphatek, Netanya, Israel).

The Airtraq SP (Prodol Meditec S.A., Guecho, Spain) is a disposable, portable, anatomically shaped, optical laryngoscope that provides a magnified view of the glottis without alignment of the oral, pharyngeal, and laryngeal axes. It includes a guiding channel to hold the ETT and direct it toward the vocal cords. It can be used for a variety of applications, including the known or predicted difficult airway, as well as for awake intubation. The Airtraq laryngoscope has been shown to result in more rapid tracheal intubation with a reduced incidence of esophageal intubation when compared to DL, especially when used by novices.[214] It is available in two adult and two pediatric sizes, as well as in specific designs for nasotracheal intubation and double-lumen tube placement. The Airtraq Avant is a newer model that features a reusable optic piece that is used in combination with disposable blades.

Lighted Optical Stylets

Lighted optical stylets are rigid or semirigid fiberoptic devices that incorporate the optical and light-transmitting components into a tubular, stainless steel sheath over which the ETT is loaded. A substantial body of evidence supports the use of these optical stylets in patients with limited neck mobility,[215] small mouth opening,[216] abnormal airway anatomy,[217] or anticipated difficult laryngoscopy.

The Bonfils retromolar intubation fiberscope (Karl Storz Endoscopy, Tuttlingen, Germany) is a 40-cm long, rigid optical stylet with a fixed anterior tip curvature of 40 degrees (Video 44.7).[218] The proximal eyepiece can be used with the naked eye or connected to a video monitor. It is available with a working channel that can be used for suction, SAYGO local anesthesia,[219] or oxygen insufflation (oxygen flow rates should be limited to 3 L/min to avoid barotrauma).[220] The Shikani optical stylet (Clarus Medical, Minneapolis, MN) is a similar device to the Bonfils fiberscope but with a malleable shaft. The Levitan FPS stylet (Clarus Medical, Minneapolis, MN) is a shorter version of the Shikani stylet intended for use in combination with DL, although usable on its own.[221] The Clarus Video System (Clarus Medical, Minneapolis, MN) is a newer version of the Shikani stylet that incorporates a liquid crystal display (LCD) screen (Video 44.8).

These optical stylets can be used on their own or in combination with DL or VAL[222] The ETT is mounted on the optical stylet and advanced under direct vision via a midline or right paraglossal route until it passes under the tongue. After indirect visualization of the tip of the stylet passing through the vocal cords (via the eyepiece or video monitor), the ETT is advanced over the stylet into the trachea. When these are not used in conjunction with DL or VAL, the left hand of the operator should lift the patient's jaw by gently grasping the mandible and displacing it anteriorly. This maneuver helps create more airspace in the oropharynx and lifts the epiglottis. Optical stylets can be used for awake intubation and have also been used for the transillumination technique (see Lighted Stylets).[218,223]

The SensaScope (Acutronic, Hirzel, Switzerland) is a hybrid rigid optical stylet that uses video chip technology. It has an S-shaped curvature and a 3-cm long steerable tip.[224] Visualization is achieved by a connection to a video monitor. The SensaScope is designed to be used in combination with DL and has been successfully used for awake intubation in patients with a predicted difficult airway.[225] The Video RIFL (AI Medical Devices, Williamston, MI) is a similar device with a rigid shaft and a flexible, steerable tip. This device features an LCD monitor attached to the handle that displays the video image.

Video Laryngoscopes

As with flexible bronchoscopes, video chip technology has begun to largely replace fiberoptic technology in rigid indirect laryngoscopes because of the advantages of a higher quality image, increased durability, and reduced maintenance costs. Over the past 15 years, VLs have revolutionized the practice of airway management, and their use may become standard not only for difficult airways, but also for routine airways as well. In fact, VAL is now included in the ASA DAA as an alternative approach to intubation and should be considered for patients with a known or predicted difficult airway.[7] A VL is also listed as a suggested piece of equipment on a portable difficult airway cart.[7]

VAL has been shown to result in improved glottic visualization, compared with DL, in both routine airway management and in the predicted difficult airway.[7,226] Although this improved visualization does not necessarily translate into increased success with intubation (particularly in the normal airway), studies have shown improved intubation success with VAL in patients with predicted difficult airways.[227,228] VLs are also useful in the unexpected difficult airway; intubation success rates of 94% and 99% have been reported for VAL as a rescue modality after failed DL.[229,230] These devices have also been successfully used for awake intubation.[231,232]

Various different VLs have been introduced, each with its own design and specific features. Generally, VLs can be divided into three groups: (1) those whose design is based on the Macintosh blade, (2) those that incorporate highly curved or distally angulated blades, and (3) those that incorporate an ETT-guiding channel.[233] Although no single design has been shown to be superior, there are certain clinical circumstances where one style may be preferable to another. Other features that vary among different VLs include the degree of portability and the size of the video monitor. Many VLs are available in both reusable and single-use models.

VLs based on the Macintosh blade design include the C-MAC laryngoscope (Karl Storz, Tuttlingen, Germany), the McGrath MAC laryngoscope (Aircraft Medical, Edinburgh, UK), and the GlideScope Titanium MAC (Verathon, Bothell, WA). These devices can be used for both DL and VAL, making them particularly useful for teaching the DL technique. The C-MAC laryngoscope is the most extensively studied of these and is associated with shorter intubation times and greater ease of use, compared with other VLs,[234,235] which is possibly due to laryngoscopists' familiarity with the use of a Macintosh-style blade (Fig. 44.26). The technique for using the C-MAC laryngoscope is identical to that of DL with a Macintosh blade; alternatively, the tip of the VL can be used to lift the epiglottis directly.[236] In contrast to other VLs, most intubations with the C-MAC laryngoscope can be performed without the use of a stylet[237,238]; the use of an oral RAE ETT can facilitate tracheal intubation.[239]

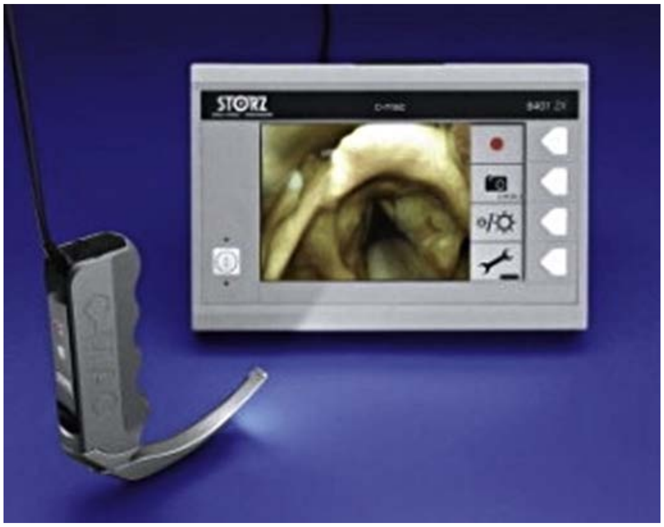

Fig. 44.26 The Storz C-MAC videolaryngoscope. (From Aziz M, Brambrink A. Video-assisted laryngoscopy. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

VLs with a distally angulated or highly curved blade permit a "look around the corner," providing an improved laryngoscopic view without requiring manipulation of the cervical spine. These devices are therefore of particular utility in patients with cervical immobilization, micrognathia, or limited mouth opening.[233] The GlideScope Titanium LoPro (Verathon, Bothell, WA) is the updated version of the archetype for this subset of devices. It possesses a 60-degree blade angulation, an antifogging mechanism, a 6.4-inch video monitor, and is available in reusable and single-use models (Fig. 44.27). The McGrath Series 5 laryngoscope (Aircraft Medical, Edinburgh, UK) is a similar device in that it possesses a distally angulated blade; its primary difference is its greater portability and a disarticulating handle that can be useful in patients with limited mouth opening and limited movement of the head and neck. The X-Blade is a hyperangulated blade for the McGrath MAC, while the D-Blade (Karl Storz, Tuttlingen, Germany) is a highly curved VL blade for use with the C-MAC system. These devices are typically inserted in the mouth midline, without sweeping the tongue from right to left as in DL. Because of the high degree of angulation of the blade, an ETT stylet is almost always necessary; malleable stylets with a 60- to 90-degree bend, articulating stylets, and the GlideRite stylet (a rigid stylet with a 90-degree curve specifically designed for use with the GlideScope) have all been successfully used with these VLs.[240,241] The VL and the styletted ETT should be inserted into the oral cavity under direct vision to avoid oropharyngeal trauma (Video 44.9).[242]

Some VLs with highly curved blades have integrated tube-guiding channels to facilitate intubation without the use of a stylet, similar to the Airtraq. The King Vision (King Systems, Noblesville, IN) and the Pentax Airway Scope (AWS; Pentax Medical, distributed by Ambu Inc., Ballerup, Denmark) fall into this category. This type of VL has been shown to be useful in patients with cervical immobilization and has been successfully used for awake intubation.[243,244]

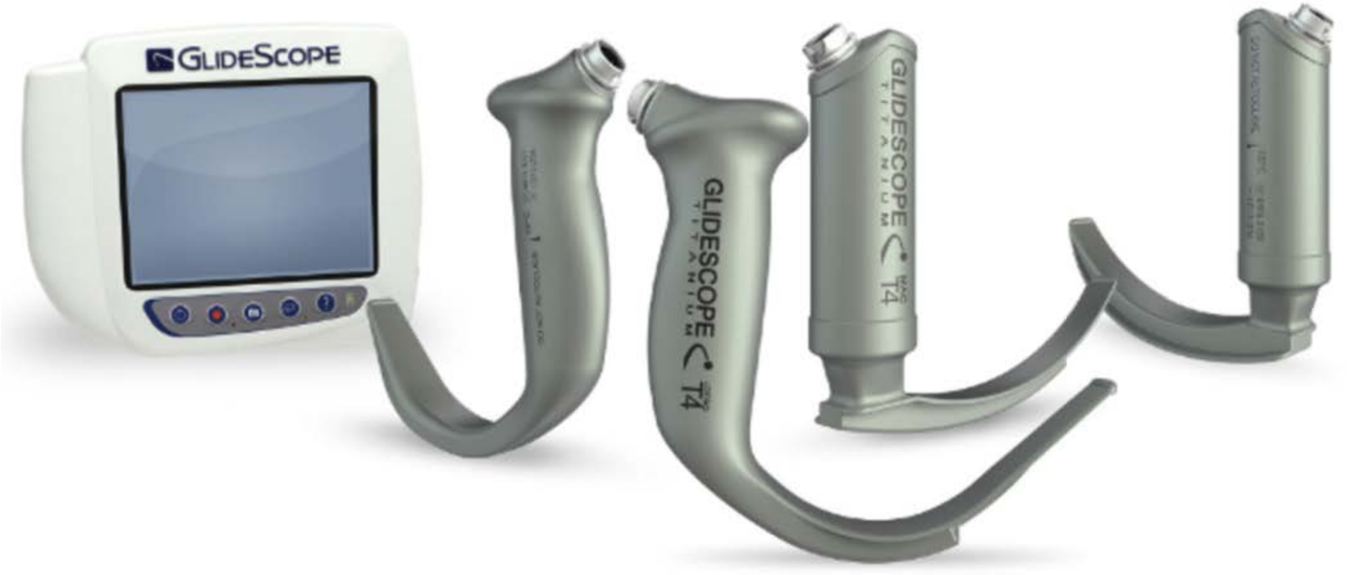

Fig. 44.27 The GlideScope AVL videolaryngoscope system with titanium blades. (From Aziz M, Brambrink A. Video-assisted laryngoscopy. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

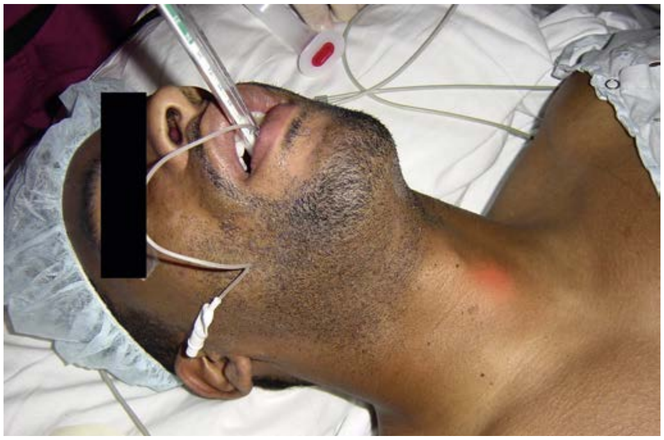

Fig. 44.28 When the tip of a lighted stylet is placed at the glottic opening, a well-circumscribed glow can be seen in the anterior neck just below the thyroid prominence.

The VividTrac (Vivid Medical, Palo Alto, CA) is a single-use, channeled VL with a Universal Serial Bus (USB) interface that works with any monitor.

Lighted Stylets

Lighted stylets make use of the transillumination technique to blindly intubate the trachea and have been described in the literature as an alternative or aid to DL, particularly in the predicted difficult airway. Lighted stylets may be particularly helpful when the presence of blood or heavy secretions limits visualization of the airway. However, because lighted stylet insertion is a blind technique, it is contraindicated in certain clinical situations, such as neoplasm of the airway or airway trauma. Because increased soft tissue leads to difficulty with transillumination, this technique is less useful in the patient who is morbidly obese.[245]

To perform the transillumination technique, an ETT is preloaded onto the stylet. The left hand of the operator lifts the supine patient's jaw by gently grasping the mandible and displacing it anteriorly to facilitate the insertion of the stylet under the tongue. The stylet should be inserted using a retromolar approach. Once inserted, the stylet should be kept midline and advanced under the tongue. A well-circumscribed *glow* (approximately the size of a quarter) should appear in the midline of the patient's neck at the level of the cricoid cartilage (Fig. 44.28), indicating correct positioning of the stylet within the trachea. Subsequently, the ETT can be advanced over the stylet into proper position (Video 44.10).[245]

RETROGRADE INTUBATION

RI is a well-described technique for orotracheal or nasotracheal intubation that involves guiding an ETT into the trachea with a narrow, flexible guide that has been percutaneously placed through the CTM into the trachea and passed retrograde through the larynx and pharynx, exiting the mouth or nose. The guide is typically a steel guidewire, although an epidural catheter can be used. This technique has several modifications, each with its own benefits and disadvantages, and can be successfully used in awake, sedated, obtunded, or apneic patients who have either an anticipated or unanticipated difficult airway.[246] Indications include failure of DL; obstruction of the view of the vocal cords by blood, secretions, or anatomic derangement; and difficult intubation scenarios such as unstable cervical spine, ankylosing spondylitis, maxillofacial trauma, or trismus. RI is also an alternative to FSI in developing countries where the availability of FISs is limited.[246]

The ASA DAA describes RI as an alternative approach to difficult intubation in the nonemergent pathway, when intubation is unsuccessful but mask ventilation is adequate. It is suggested that equipment for RI be included in a portable storage unit for difficult airway management. RI can take several minutes to accomplish; therefore this technique is contraindicated in an emergent CICV scenario.[246] Other contraindications are generally relative and include anatomic abnormalities (e.g., malignancy, goiter) that preclude access to the CTM, tracheal stenosis at the level of the CTM, coagulopathy, and local infection.

The ideal position for RI is supine with the neck in extension, allowing easy palpation of the cricoid cartilage and surrounding structures. If this position is not possible, then RI can also be performed with the patient in the sitting position or with the neck in a neutral position. If landmarks are difficult to identify, then ultrasound guidance may be used. The anterior neck should be cleansed before puncture, and aseptic technique should be used. The translaryngeal puncture site can be performed superior or inferior to the cricoid cartilage. The CTM (superior to the cricoid cartilage) has the advantage of being relatively avascular; however, a puncture at this site allows only 1 cm of space below the level of the vocal cords for the tip of the ETT. A puncture site inferior to the cricoid cartilage, at the cricotracheal ligament, allows the ETT to travel in a straight path with a long length of the ETT below the vocal cords; however, this site is associated with a greater potential for bleeding.[246]

The classic technique for RI involves using a Tuohy needle to puncture the CTM and an epidural catheter as the guide. More commonly, an IV catheter and a steel guidewire are used. The diameter of the guidewire should be small enough to fit through the IV catheter and should be at least twice as long as the ETT to be used; a guidewire with a .038-inch diameter (which passes through an 18-gauge IV catheter) and a length of 110 cm is commonly used. Commercial kits are available that include all necessary equipment. Performing a RI with a J-tip, steel guidewire rather than an epidural catheter provides the following advantages: the J-tip of a guidewire is less traumatic to airway, the guidewire has a lower tendency to coil or kink, retrieval of the guidewire from the oral or nasal cavity is easier, and the technique is quicker.[246]

Once the patient has been positioned, the operator's nondominant hand stabilizes the trachea by placing the thumb and third digit on either side of the cricoid cartilage. The index finger is used to identify the midline of the CTM and the upper border of the cricoid cartilage. A syringe half-filled with saline is attached to an 18-gauge angiocatheter and advanced at a 90-degree angle to the CTM with the bevel facing cephalad, aspirating for air bubbles to confirm the position inside the trachea. The angle of insertion is slightly lowered, and the needle is removed. At this stage, reconfirmation of a position within the trachea and instillation of a local anesthetic can be performed with a second syringe filled with 2 to 4 mL of 2% or 4% lidocaine. This transtracheal block can provide additional comfort to a patient who is awake or sedated and undergoing RI, or it can reduce the incidence of sympathetic stimulation and laryngospasm in a patient under general anesthesia.

The guidewire is then advanced through the angiocatheter until it exits the mouth or nose. DL can be used to facilitate the wire exiting the mouth, if necessary. The guidewire is clamped with a hemostat at the level of the skin of the neck to prevent migration. Although the ETT can then be directly advanced over the guidewire, a tapered guide catheter (e.g., Arndt airway exchange catheter) is useful to reduce the discrepancy in diameter between the guide-wire and the ETT, which can predispose the ETT to catch on the arytenoids or vocal cords rather than smoothly slide into the trachea. The guide catheter is placed over the portion of the wire exiting the mouth or nose and advanced until it contacts the CTM. The wire is then removed, and an ETT is advanced over the guide catheter (Fig. 44.29 and Video 44.11). Potential complications include bleeding (usually minimal), subcutaneous emphysema, pneumomediastinum, pneumothorax, and injury to the posterior trachea or esophagus.[246]

DOUBLE-LUMEN TUBES AND BRONCHIAL BLOCKERS

Single-lung ventilation is required for certain clinical circumstances, including protective lung isolation from infection or hemorrhage, attaining adequate exposure for surgical procedures (e.g., video-assisted thoracoscopy), and for controlling the distribution of ventilation in the setting of major bronchial surgery, trauma, or fistula. Double-lumen tubes (DLTs) and bronchial blockers are two options that allow for ventilation of only one lung (also see Chapter 53).

DLTs have a bronchial lumen and a tracheal lumen. They are designated as left-sided or right-sided, depending on whether the bronchial lumen goes to the left or right main bronchus. Most commonly, a left-sided DLT is used to avoid blockage of the right upper lobe bronchus. DLTs are placed in a similar fashion to the standard ETT, although placement is usually more difficult because of their size and stiffness. Video laryngoscopy can facilitate DLT placement.[247] After placing the DLT into the trachea, verification of the location of the bronchial port with an FIS should be determined. The blue bronchial cuff should be positioned just below the carina in the appropriate bronchus. Inflation of the blue bronchial balloon under direct visualization helps verify proper placement. Care should be taken to ensure that the bronchial cuff does not herniate over the carina. The VivaSight-DL (Ambu Inc., Ballerup, Denmark) is a single-use left-sided DLT with an integrated camera located at the tip of the tracheal lumen and allows for accurate positioning of the DLT without the use of an FIS. Once a DLT is properly placed, isolating a lung is possible by inflating the bronchial cuff and clamping either the tracheal or bronchial connector.

Bronchial blockers are essentially hollow, balloon-tipped catheters that are endobronchially placed to isolate and deflate one lung. In some clinical situations, lung isolation is required, but the use of a DLT is not practical because of a difficult airway, decreased size of the tracheal lumen, or the need for postoperative mechanical ventilation. In these instances, the use of a modified single-lumen tube with an integrated bronchial blocker (e.g., the Univent [Fuji Systems, Tokyo, Japan]) or the use of a bronchial blocker in conjunction with a standard ETT is appropriate.

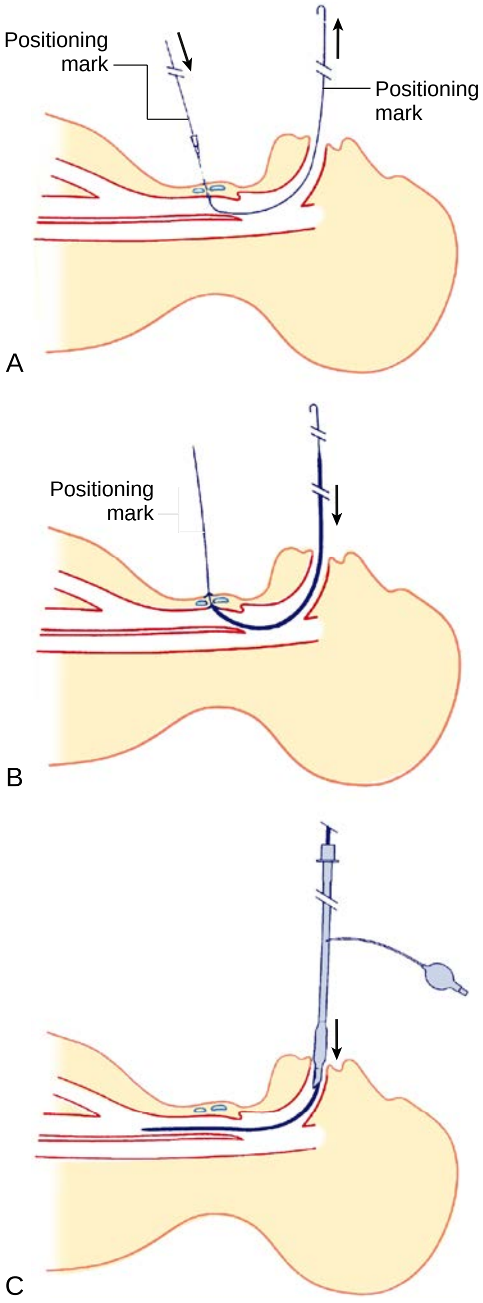

Fig. 44.29 The guidewire technique for retrograde intubation. (A) After the placement of an 18-gauge angiocatheter through the cricothyroid membrane, the J-tip of the guidewire is inserted in a cephalad direction until it exits the mouth or nose. (B) The guide catheter is threaded over the guidewire until it contacts the laryngeal access site. The guidewire is then removed from above. (C) After advancing the guide catheter 2 to 3 cm, the endotracheal tube is advanced into the trachea. (Courtesy Cook Critical Care, Bloomington, IN.)

COMBINATION TECHNIQUES

Tracheal Intubation Through a Supraglottic Airway Device

The intubating LMA (ILMA), known as the LMA Fastrach (LMA North America, San Diego, CA), was first described

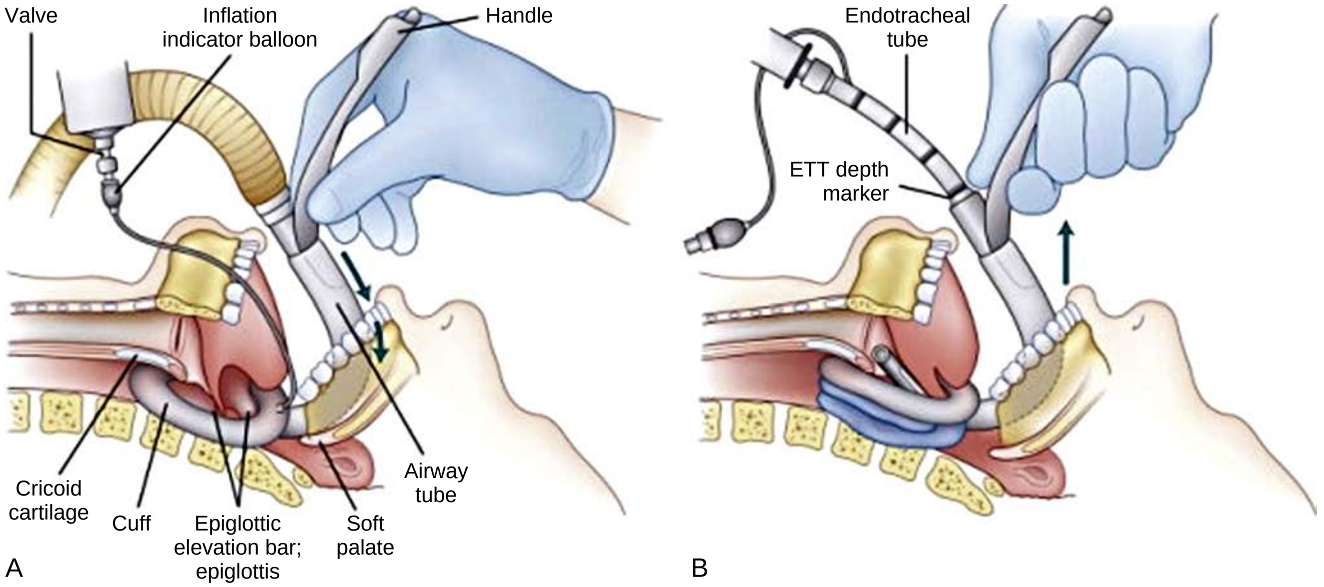

Fig. 44.30 The Chandy maneuver consists of two steps. (A) The first step is important for establishing optimal ventilation. The intubating laryngeal mask airway (ILMA) is slightly rotated in the sagittal plane using the handle until the least resistance to bag ventilation is achieved. (B) The second step is performed just before blind intubation. The handle is used to lift (but not tilt) the ILMA slightly away from the posterior pharyngeal wall, which facilitates the smooth passage of the endotracheal tube into the trachea. (From Lindsay HA, Cook TM, Russo SG, Hagberg CA. Supraglottic airway techniques: laryngeal mask airways. In: Hagberg CA, Artime CA, Aziz M, eds. *Hagberg and Benumof's Airway Management*. 4th ed. Philadelphia: Elsevier; 2018.)

by Dr. Archie Brain in 1997; it became available for commercial use in the United States shortly thereafter. The ILMA was designed as a conduit for tracheal intubation to facilitate ventilation between attempts at tracheal intubation. The rigid handle and airway tube enable a rapid and precise control of mask position. An epiglottic elevating bar is designed to elevate the epiglottis as the tube is advanced into the bowl. A disposable, single-use version is available in addition to the original reusable model. Specialized reusable or single-use tracheal tubes are designed to facilitate atraumatic blind intubation through the ILMA. The tubes are straight, wire-reinforced, and have a soft molded tip designed to prevent impingement on laryngeal structures.

The technique of inserting the ILMA differs in many respects from the insertion of the cLMA, and the learning curve is significant. A neutral head position (nonextended head on a support) is recommended. The ILMA handle is used to rotate the mask into the pharynx. Oxygenation, ventilation, and anesthesia are stabilized after insertion. If resistance to ventilation is encountered, then the position of the ILMA is adjusted. The *Chandy maneuver* consists of two separate maneuvers: (1) the ILMA is rotated in the sagittal plane until resistance to bag ventilation is minimal; and then (2) the ILMA is gently lifted from the posterior pharyngeal wall just before passage of the tracheal tube (Fig. 44.30). The original, reusable ILMA should be removed soon after tracheal intubation has been verified because its rigidity results in high pressure on adjacent tissues. Although the blind technique has a high rate of success, intubation under vision with an FIS through the ILMA achieves higher first-attempt and overall success rates.

Other SGAs can be used to facilitate tracheal intubation. The cLMA, although not designed for intubation, can be an effective conduit if used in conjunction with an FIS. Because of the long and narrow airway shaft, a microlaryngeal tube must be used. Alternatively, a cLMA can be exchanged for an ETT by using an FIS in conjunction with the Aintree intubation catheter (Cook Critical Care, Bloomington, IN), which is a hollow airway exchange catheter designed to fit over a standard FIS (Fig. 44.31 and Video 44.12). Most newer SGAs have airway shafts that are wide enough to allow intubation through the device with a standard-sized ETT (Video 44.13).

Combined Direct Laryngoscopy Techniques

DL can be used to expand the space available in the oral cavity to manipulate an FIS by displacing pharyngeal tissue, and the epiglottis can be elevated allowing the scope to be more easily directed underneath the epiglottis toward the glottic opening. This may be especially helpful in the morbidly obese patient or patients with soiled airways (e.g., with blood, secretions, or vomitus).[248]

When a Cormack-Lehane grade III view is encountered during DL, the coudé tip of an ETT introducer can be passed underneath the epiglottis, and tracheal positioning confirmed by the sensation of clicks as the bougie tip passes the tracheal rings.

While using an optical stylet as an adjunct to DL, the tip of the stylet can be guided just beneath the tip of the epiglottis under direct vision. While holding the ETT/fiberoptic stylet securely, the clinician transfers his/her vision to the eyepiece or monitor where the glottic opening can be visualized, and the ETT can be advanced through the vocal cords and into the trachea.[248]

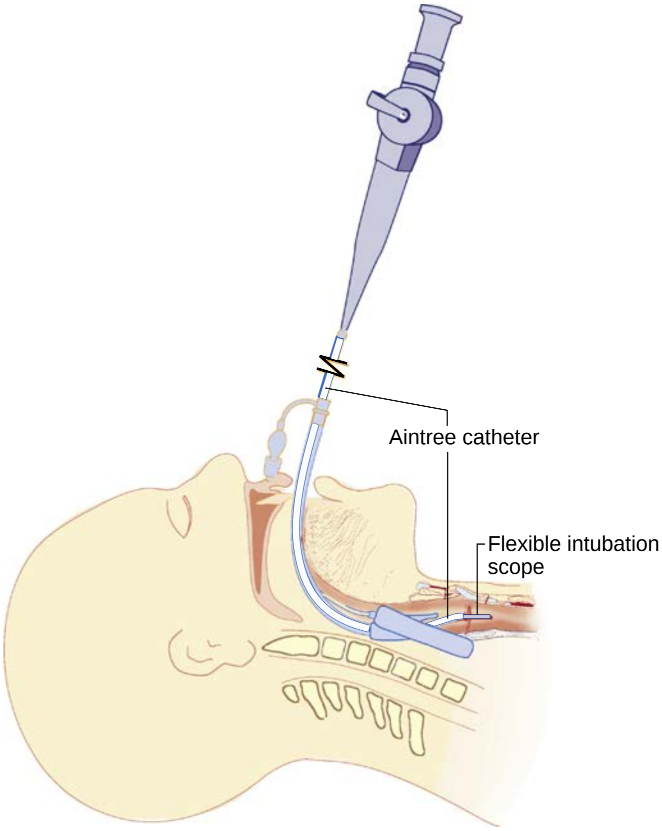

Fig. 44.31 Aintree intubating catheter within a flexible intubation scope, inserted through a laryngeal mask airway. (From Henderson J. Airway management. In: Miller RJ, ed. *Anesthesia.* 7th ed. Philadelphia: Churchill Livingstone; 2009.)

Combined Video-Assisted Laryngoscopy Techniques

Just as the bougie has been demonstrated to be an invaluable adjunct to DL, it may be used in combination with VAL in order to improve the success of tracheal intubation, and may offer additional advantages. In a trial featuring a simulated airway with vomitus, the use of a bougie improved intubation success rate and decreased the time to intubation with the Pentax-AWS and the McGrath MAC compared to DL.[249] A bougie may also facilitate advancement of the ETT into the trachea when an adequate view is obtained with VAL, but difficulty is encountered with intubation (Video 44.14).[250]

Optical stylets can also be used in combination with VAL. A study examining the use of the C-MAC VL and the Bonfils Intubation Scope in patients with a history of difficult intubation found that the combination of the two devices was superior in terms of glottic view than either device by itself.[251]

Certain circumstances may arise in which a combination of VAL and FSI may be beneficial. A patient with severely limited mouth opening and/or unstable cervical spine injury may preclude the use of DL in order to assist in FSI; using VAL in this situation may provide the ability to view the glottic opening and better guide the FIS into position. VAL can also diagnose difficulties with the passage of the ETT over the FIS into the glottis (Video 44.15).[248]

Combined Retrograde Intubation Techniques

To improve the success of retrograde intubation, it can be combined with DL or an FIS. DL can be used as an adjunct in order to improve success during retrograde guided intubation. During the classic technique of retrograde intubation, after a catheter is placed in the inferior cricothyroid membrane, the J-tip of a guidewire is directed upward until it can be retrieved from the mouth or nares. If orotracheal intubation is desired, DL can aid the clinician in opening the oropharynx and visualizing the wire so that it may be retrieved more easily through the mouth prior to entering the nasopharynx. In addition, after the guiding catheter is advanced anterograde over the wire until tenting is noted at the cricothyroid access point, DL may be used in order to lift the epiglottis and pharyngeal tissue, facilitating the passage of an ETT through the vocal cords.[248]

Alternatively, an FIS can be used to facilitate retrograde intubation. After the guidewire is retrieved from the mouth or naris, it is passed through the working channel of the FIS from distal to proximal. The FIS is then passed over the guidewire and into the glottis until resistance is met at the cricothyroid membrane. The hemostat that held the guidewire in place internally may now be released and the guidewire removed. The FIS may then be advanced until the carina is visualized and the ETT is passed into the trachea. In this fashion, the FOB reduces the likelihood that the ETT will become dislodged and the airway can be visualized throughout the procedure. There are several advantages to passing a FOB antegrade over a retrograde placed wire[248]:

- The outer diameter of the guidewire and the internal diameter of the fiberoptic suction port form a tight fit that allows the FOB to follow a straight path through vocal cords without impinging on anatomic structures.
- The FIS acts as large antegrade guide catheter and allows easy passage of the ETT.
- It allows placement of the ETT under direct visualization.
- The FIS may be advanced to the carina freely (past the puncture site) which eliminates the problem of distance between vocal cords and puncture site.

Emergency Front of Neck Access

Emergency FONA refers to rescue techniques used in a CICO situation when attempts at establishing a noninvasive airway have failed. These techniques may also be used as a primary airway in some difficult airway situations when attempts at securing a noninvasive airway are likely to fail, such as a patient with a laryngeal neoplasm and critical airway obstruction. Options for FONA include transtracheal jet ventilation (TTJV), cricothyrotomy, and tracheostomy. Whereas tracheostomy is usually performed by a surgeon, the anesthesia practitioner should become proficient with the techniques for TTJV and cricothyrotomy; the situation will inevitably arise in which an invasive airway will become necessary. An emergent situation is not the time to become familiar with a new technique.

TRANSTRACHEAL JET VENTILATION

Percutaneous TTJV is a relatively quick and effective but invasive method of oxygenation and ventilation in the CICV scenario when more conservative measures fail. The ASA DAA lists TTJV as an emergent invasive technique to be used in patients who cannot be conventionally ventilated or intubated.[7] TTJV is widely regarded as a life-saving procedure that can provide adequate, temporary oxygenation and ventilation with less training and complications than a surgical airway, the last resort for obtaining an airway in the algorithm.[252] Nonetheless, TTJV is an invasive technique, and its primary use is as an emergency airway. Occasionally, it is used on an elective basis for laryngeal surgery.

Inspiration during TTJV is achieved by insufflation of pressurized oxygen through a cannula placed by needle cricothyrotomy. Expiration is passive as a result of the elastic recoil of the lungs and the chest wall. Allowing sufficient time for passive expiration to avoid barotrauma from breath stacking is essential. Expiration occurs through the glottis and depends on a nonobstructed upper airway, which is imperative to avoid barotrauma and resulting pneumothorax. The egress of air through the glottic aperture can also provide bubbles to facilitate the placement of an ETT. In fact, several case reports have demonstrated that after the initiation of TTJV in an airway with little or no visualization of the glottis, successful intubation occurred because of the opening of the glottis and guidance from the bubbles with jet ventilation.

TTJV should not be performed in patients who have sustained direct damage to the cricoid cartilage or larynx or in patients with complete upper airway obstruction. Other relative contraindications to TTJV include coagulopathy, obstructive pulmonary disease, or distorted anatomy in which catheter placement might be difficult.

Typically, a 12- to 16-gauge kink-resistant catheter is used for TTJV. A coil-reinforced 6Fr catheter (Cook Critical Care, Bloomington, IN) is specifically designed for TTJV to prevent kinking, and its Teflon coating facilitates its passage through the CTM into the trachea. The technique for placement is similar to the technique for RI, with the exception that the needle is inserted with the bevel facing caudally. Confirmation of proper intratracheal placement of the catheter by testing for aspiration of air is imperative before initiating jet ventilation.

The minimum pressure required to drive a jet ventilator is 15 psi. The pipeline pressure for oxygen in hospitals in the United States is approximately 55 psi. Commercially available jet ventilators generally contain pressure regulators to lower the pipeline pressure to provide successful jet ventilation while avoiding higher pressures that might result in barotrauma. In most instances in the operating room, adequate pressure for jet ventilation can be achieved by connecting straight to the pipeline supply. Difficulty usually arises in locations outside of the surgical unit where TTJV may be needed but adequate driving pressure is not available.[252]

A major complication of TTJV is barotrauma with resulting pneumothorax from the use of high-pressure oxygen. To prevent this complication, ensuring that a path for air egress exists and that adequate time for passive expiration is available is an absolute necessity. The lowest possible pressure that will provide adequate oxygenation and ventilation should be used. Other complications associated with TTJV include subcutaneous or mediastinal emphysema, hemorrhage, aspiration, and perforation of the posterior wall of the trachea or esophagus.[252]

The Ventrain is a single-use, manually operated oxygen insufflation device designed to decrease the risk of barotrauma when compared to TTJV through a small-bore percutaneous catheter.[253] It uses the Bernoulli principle to provide expiratory ventilation assistance, meaning that negative pressure is generated that facilitates the egress of gas, and therefore can even be used when the upper airway is obstructed.[254] It is driven by oxygen from a high-pressure source with a controllable flow, e.g., a wall-mounted flowmeter or an oxygen cylinder with a flow regulator.

CRICOTHYROTOMY

Cricothyrotomy is an invasive technique that provides access to the airway in situations when either noninvasive maneuvers have failed or when it is clinically indicated as a primary plan to secure the airway.[255] Cricothyrotomy is included in the ASA DAA as an emergent invasive technique after other rescue maneuvers have failed or are not feasible. Cricothyrotomy equipment should be included in all emergency airway storage units and readily available. Cricothyrotomy is not considered a permanent airway, and, after placement, plans should be made for either the removal of the cricothyrotomy catheter or conversion to a formal tracheostomy.[255]

In children younger than 6 years of age (also see Chapter 77), the cricoid cartilage is the narrowest portion of the airway and the isthmus of the thyroid gland typically reaches the level of the CTM; therefore cricothyrotomy is contraindicated. Needle cricothyrotomy with TTJV is indicated in this pediatric population. Other contraindications to cricothyrotomy include laryngeal fractures, laryngeal neoplasm, subglottic stenosis, coagulopathy, and distorted or unidentifiable neck anatomy.

The two most common techniques for performing a cricothyrotomy are the percutaneous dilational cricothyrotomy and the surgical cricothyrotomy. For the anesthesiologist, the percutaneous technique has historically been preferred because of the familiarity of using the Seldinger technique for other procedures (e.g., central venous catheterization). Recently, however, surgical cricothyrotomy has been advocated as the preferred technique due to its faster speed and higher reliability.[8]

A number of surgical methods for cricothyrotomy have been described; however, the scalpel-bougie technique is the preferred technique in the Difficult Airway Society guidelines for management of the difficult airway. The process is outlined in Box 44.4 and Fig. 44.32. It is recommended that all anesthesiologists learn this technique and receive regular training to avoid fading of skill.[8]

A number of commercially available cricothyrotomy kits use the percutaneous dilational technique. The basis for this procedure is the insertion of an airway catheter over a dilator that has been inserted over a guidewire. The patient's neck is extended, and the cricothyroid groove is identified. If landmarks are difficult to identify, then

BOX 44.4 **Surgical Cricothyrotomy**

Equipment

- No. 10 scalpel
- Bougie with a coudé (angled) tip
- Cuffed endotracheal tube (ETT) with a 6-mm internal diameter

Technique

1. Stand on the patient's left-hand side if you are right handed (reverse if left handed).
2. Stabilize the larynx using the left hand.
3. Use the left index finger to identify the cricothyroid membrane (CTM). If the CTM is not palpable, make a 8-10 cm vertical incision in the midline and use blunt dissection with the fingers of both hands to separate tissues and identify and stabilize the larynx with the left hand.
4. Holding the scalpel in your right hand, make a transverse stab incision through the skin and cricothyroid membrane with the cutting edge of the blade facing toward you.
5. Keep the scalpel perpendicular to the skin and turn it through 90° so that the sharp edge points caudally (toward the feet).
6. Swap hands; hold the scalpel with your left hand.
7. Maintain gentle traction, pulling the scalpel toward you (laterally) with the left hand, keeping the scalpel handle vertical to the skin (not slanted).
8. Pick the bougie up with your right hand.
9. Holding the bougie at a right angle to the trachea, slide the coudé tip of the bougie down the side of the scalpel blade furthest from you into the trachea.
10. Rotate and align the bougie with the patient's trachea and advance gently up to 10-15 cm.
11. Remove the scalpel.
12. Stabilize trachea and tension skin with left hand.
13. Railroad a lubricated size 6.0 mm cuffed tracheal tube over the bougie.
14. Rotate the tube over the bougie as it is advanced. Avoid excessive advancement and endobronchial intubation.
15. Remove the bougie.
16. Inflate the cuff and confirm ventilation with capnography.

Modified from Frerk C, Mitchell VS, McNarry AF, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth.* 2015;115(6):827–848.

ultrasound guidance may be used. A 1- to 1.5-cm vertical incision is made through the skin overlying the CTM. An 18-gauge needle-catheter attached to a fluid-filled syringe is passed through the incision at a 45-degree angle in the caudal direction with continuous aspiration. Because of the location of the cricothyroid artery and the proximity of the CTM to the vocal folds, puncture of the CTM should be made in the lower third of the membrane and directed inferiorly (Fig. 44.33).[255] Aspiration of free air confirms passage through the CTM. The catheter is advanced over the needle into the trachea. The needle is removed, and the catheter is left in place. The guidewire is inserted caudally to a depth of approximately 2 to 3 cm. The catheter is removed, and the curved dilator with the airway cannula is threaded over the guidewire. The dilator and cannula unit is advanced through the CTM while maintaining control of the guidewire. The dilator and guidewire are removed together while the cannula remains in place. The cuff is inflated, and ventilation is attempted. Proper placement is confirmed by capnography, and the airway cannula is secured in place (Video 44.16).[255]

Complications include hemorrhage, injury to the posterior tracheal wall or esophagus, vocal cord injury, laceration of the thyroid gland, and improper insertion of the cannula. Placement of the airway cannula in the subcutaneous tissue can result in subcutaneous or mediastinal emphysema. Late complications from cricothyrotomy include swallowing dysfunction, infection, voice changes, and tracheal stenosis. Tracheal stenosis has an incidence of approximately 2% to 8% in adults and is more likely if preexisting trauma or infection is present.

Extubation of the Trachea

A critical component of airway management is the process of extubation. Although considerable emphasis is placed on the problems that can arise during induction and intubation, the risk of complications can potentially be higher during extubation of the trachea.[256] Analysis of the ASA Closed Claims database has shown that although the number of claims for death and brain damage during intubation have decreased since the adoption of the ASA *Practice Guidelines for Management of the Difficult Airway*, the number of claims arising from injury at extubation and during recovery have not decreased.[1] In response to these trends and in the absence of any well-established strategies for the management of tracheal extubation, the DAS established a set of guidelines in 2012 to "discuss the problems arising during extubation and recovery" and to "promote a strategic, stepwise approach to extubation."[257]

A number of complications can arise during extubation (Box 44.5); although some of these complications are minor with no long-term sequelae, others can lead to a failed extubation. Failed extubation can result from the failure of oxygenation, failure of ventilation, inadequate clearance of pulmonary secretions, or loss of airway patency.[84] If an airway is not quickly reestablished, then serious complications, including death, may result. As such, the anesthesia practitioner needs to stratify extubation risk preemptively and establish an extubation plan before attempting extubation. Per the DAS guidelines, risk stratification can be accomplished by considering the following: (1) whether the airway was normal and uncomplicated at induction; (2) whether the airway has become difficult to manage as a result of surgical changes, trauma, or nonsurgical factors; and (3) whether the patient has general risk factors for an unsuccessful extubation.[257]

GENERAL CONSIDERATIONS FOR EXTUBATION OF THE TRACHEA

For both routine and difficult extubation scenarios, an extubation plan must be preemptively formulated, including a plan for reintubation that can be implemented should the patient be unable to maintain an adequate airway after extubation.[7] The decision of whether to extubate the trachea when the patient is fully awake versus a deep extubation before the return of consciousness should be made based on the risks and benefits of each technique. The awake patient can more easily maintain a patent airway, attributable to the recovery of awake pharyngeal muscle tone and airway reflexes. Deep extubation avoids coughing

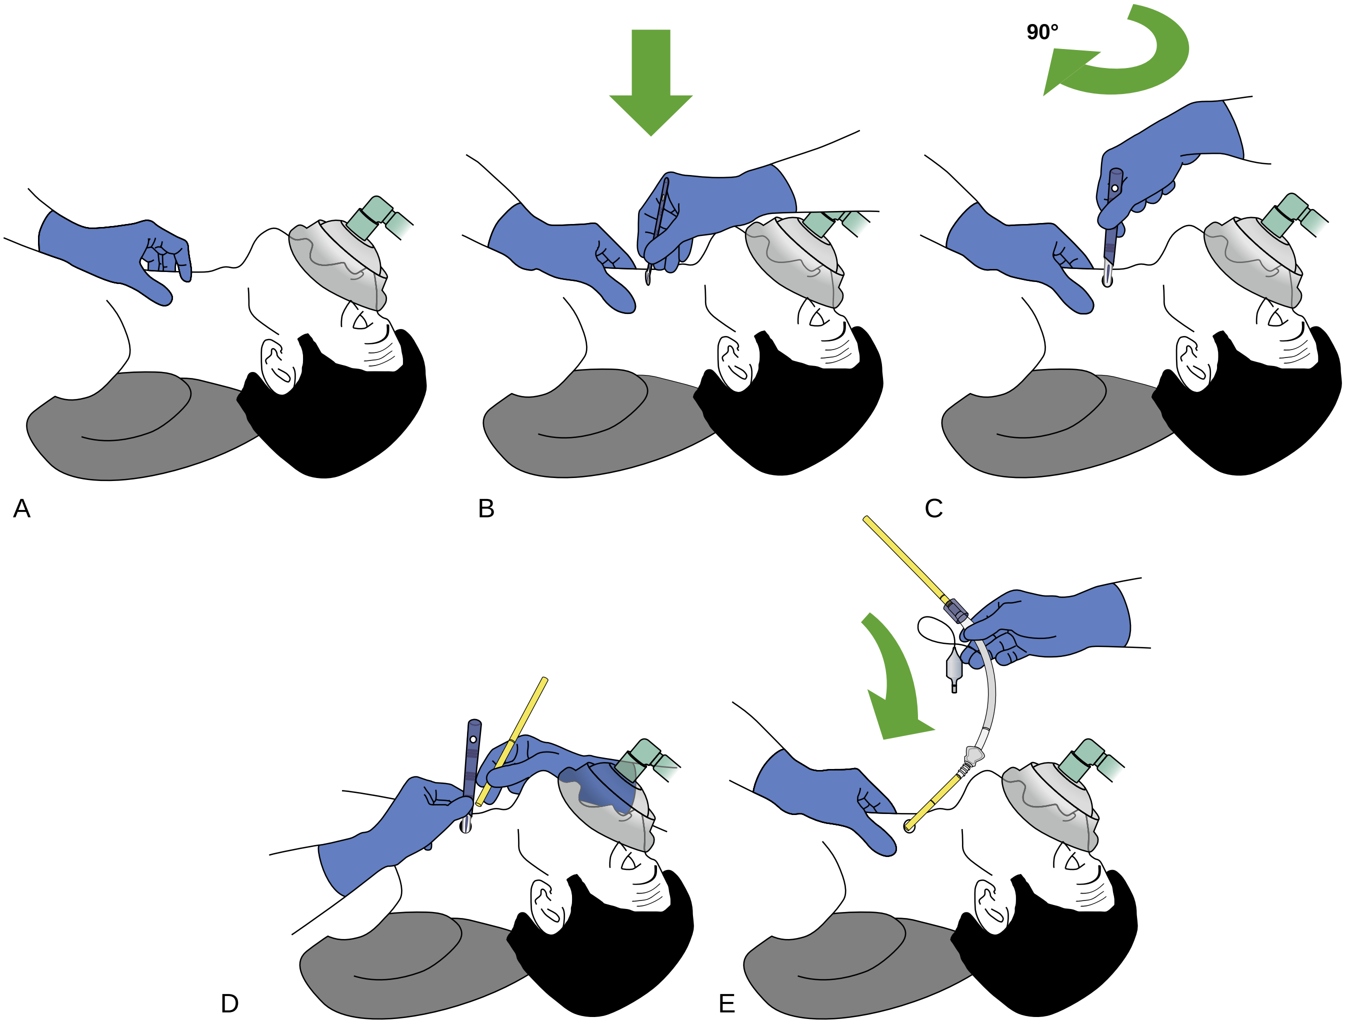

Fig. 44.32 Scalpel-bougie technique—"stab, twist, bougie, tube." (A) Identify the cricothyroid membrane (CTM). (B) Make a transverse stab incision through the CTM. (C) Rotate the scalpel so that the sharp edge points caudally. (D) Pulling the scalpel toward you to open up the incision, slide the coudé tip of the bougie down the scalpel blade into the trachea. (E) Advance the endotracheal tube into trachea. (From Frerk C, Mitchell VS, McNarry AF, et al. Difficult Airway Society 2015 guidelines for management of unanticipated difficult intubation in adults. *Br J Anaesth*. 2015;115(6):827–848.)

and adverse hemodynamic effects but risks upper airway obstruction and hypoventilation. An alternative extubation technique, known as the Bailey maneuver, involves exchanging an ETT for an SGA while the patient is under deep anesthesia.[258] Extubation during a light plane of anesthesia (stage II) can increase the risk for laryngospasm and other airway complications and should be avoided.

General preparations for extubation should include ensuring adequate reversal or recovery from neuromuscular blockade, hemodynamic stability, normothermia, and adequate analgesia. Patients should be preoxygenated with a 100% fraction of inspired oxygen concentration (F_{IO_2}), and alveolar recruitment maneuvers should be considered if appropriate. Suctioning of the pharynx (and the trachea, if indicated), the removal of throat packs, and the placement of a bite block should be performed while the patient is under deep anesthesia.[22] Bite blocks are essential for an awake intubation to prevent biting of the tube during emergence, which can result in airway obstruction and the development of negative-pressure pulmonary edema. Oropharyngeal airways are not recommended for use as a

Box 44.5 **Complications Associated with Extubation**

- Laryngospasm and bronchospasm
- Upper airway obstruction
- Hypoventilation
- Hemodynamic changes (hypertension, tachycardia)
- Coughing and straining, leading to surgical wound dehiscence
- Laryngeal or airway edema
- Negative-pressure pulmonary edema
- Paradoxical vocal cord motion
- Arytenoid dislocation
- Aspiration

Box 44.6 **Factors Associated with Increased Extubation Risk**

Airway Risk Factors

- Known difficult airway
- Airway deterioration (bleeding, edema, trauma)
- Restricted airway access
- Obesity and obstructive sleep apnea
- Aspiration risk

General Risk Factors

- Cardiovascular disease
- Respiratory disease
- Neuromuscular disease
- Metabolic derangements
- Special surgical requirements

Modified from Popat M, Mitchell V, Dravid R, et al. Difficult Airway Society guidelines for the management of tracheal extubation. *Anaesthesia.* 2012;67:318–340.

bite block because they can result in dental damage; rather, taped, rolled gauze securely inserted between the molars should be used.[259]

Gastric insufflation with air can increase the risk of pulmonary aspiration after extubation and can impede ventilation. Patients in whom mask ventilation with high pressures is necessary should have an orogastric tube placed and suctioned before extubation.

The sniffing position is the standard position for extubation; its major advantage is that the patient is optimally positioned for airway management, if necessary. Patients who are morbidly obese and other patients at risk for hypoventilation and airway obstruction can benefit from extubation in the head-up position. The lateral decubitus position may be the preferred option when the risk for pulmonary aspiration is high.[22]

Application of positive pressure immediately before cuff deflation may help expel secretions that have collected above the ETT cuff. Inspection of the pilot balloon to ensure complete cuff deflation before extubation is essential; extubation with an inflated cuff can cause vocal cord injury or arytenoid dislocation.

EXTUBATION AND REINTUBATION OF THE DIFFICULT AIRWAY

Many surgical and anesthetic factors can increase extubation risk. A summary of the most pertinent factors is listed in Box 44.6. Although several techniques can be used to manage extubation of the difficult airway, including the Bailey maneuver and remifentanil infusion,[257] the use of an airway exchange catheter (AEC) is most common and recommended by the ASA's Task Force on Management of the Difficult Airway. This hollow reintubation guide is passed through the ETT before extubation and kept in situ until the possible need for reintubation has passed. AECs have the additional capability of maintaining oxygenation or monitoring respiration by connection to a capnograph. Smaller AECs (11Fr) are generally well-tolerated by awake patients, who can breathe, talk, and cough around them. They should be secured with tape in place to prevent accidental dislodgement and labeled to distinguish them from traditional feeding tubes, which can have a similar appearance. Reintubation over an AEC, if necessary, can be facilitated by gentle DL to retract the tongue and oropharyngeal soft tissue.

Dissemination of Critical Airway Information

As stated earlier, one of the most predictive factors for difficult intubation is a history of previous difficulty with intubation. Therefore it is crucial that critical airway information be documented and disseminated in such a way that clinicians who subsequently care for a patient with a difficult airway be alerted to the history and obtain the necessary information to safely manage the patient's airway. The ASA Practice Guidelines for Management of the Difficult Airway recommend the that clinicians document the difficulty with airway management and inform the patient or responsible person of the difficulty encountered.[7] Consideration of notification systems, such as a written report or letter to the patient, a written report in the medical chart, communication with the patient's surgeon or primary caregiver, a notification bracelet or equivalent identification device, and/or chart flags is recommended.

In 1992, the MedicAlert Foundation National Difficult Airway/Intubation Registry was created to standardize the documentation and dissemination of critical airway information. By 2010, more than 11,000 patients were included in the registry.[260] Patients with a difficult airway should be directed to the MedicAlert website.

Summary

Airway management is at the core of safe anesthetic practice. The anesthesia practitioner must have a fundamental knowledge of airway anatomy, physiology, and pharmacology, and well-developed skills in the use of a wide variety of airway devices. Although most airways are straightforward, management of the difficult airway remains one of the most relevant and challenging tasks for anesthesia care providers. Prediction and anticipation of the difficult airway and the formulation of an airway management plan are essential. Many airway problems can be solved with relatively simple devices and techniques; however, experience and good clinical judgment are necessary for their successful application. Newer airway devices with the potential to improve patient outcomes are continually being developed. Anesthesia providers must concurrently develop their skills and learn new techniques to be prepared when difficulty presents itself. Competency-based training with routine assessment of clinical ability with airway techniques is likely in the future for all practitioners involved in airway management. Expertise comes from dedicated practice and a commitment from the practitioner for career-long learning.

Spinal, Epidural, and Caudal Anesthesia

RICHARD BRULL, ALAN J.R. MACFARLANE, and VINCENT W.S. CHAN

KEY POINTS

- The distal termination of the spinal cord varies from L3 in infants to the lower border of L1 in adults.
- The speed of neural blockade depends on the size, surface area, and degree of myelination of the nerve fibers exposed to the local anesthetic.
- Blockade of the peripheral (T1-L2) and cardiac (T1-T4) sympathetic fibers is responsible for the decrease in arterial blood pressure (cardiac output and systemic vascular resistance) associated with neuraxial techniques.
- Cerebrospinal fluid volume and local anesthetic baricity are the most important determinants for the spread (i.e., block height) of spinal anesthesia.
- The use of smaller-gauge spinal needles decreases the incidence of post–dural puncture headache.
- Serious neurologic complications associated with neuraxial blockade are rare, but the risk increases in the elderly and those with preexisting spinal pathology.
- The use of low-molecular-weight heparin and potent platelet inhibitors increases the risk of epidural hematoma from neuraxial blockade.
- Epidural blood patches are greater than 90% effective in relieving post–dural puncture headache.
- Local anesthetic systemic toxicity results from unintentional administration of the drug into an epidural vein.
- Use of neuraxial blockade, particularly when used as the sole anesthetic, can reduce perioperative morbidity and may reduce mortality.

Principles

Spinal, epidural, and caudal neuraxial blocks result in one or a combination of sympathetic blockade, sensory blockade, or motor blockade depending on the dose, concentration, or volume of local anesthetic administered. Despite these similarities, there are significant technical, physiologic, and pharmacologic differences. Spinal anesthesia requires a small mass (i.e., volume) of drug that is almost devoid of systemic pharmacologic effects to produce rapid (<5 minutes), profound, reproducible sensory analgesia. In contrast, epidural and caudal anesthesia progress more slowly (>20 minutes) after a large mass of local anesthetic that produces pharmacologically active systemic blood levels, which may be associated with side effects and complications unknown to spinal anesthesia. The introduction of combined spinal and epidural techniques blurs some of these differences, but also adds flexibility to clinical care.

Practice

Neuraxial blockade has a wide range of clinical applications for surgery, obstetrics, acute postoperative pain management, and chronic pain relief. Single-injection spinal or epidural anesthesia with local anesthetic is most commonly used for surgery to the lower abdomen, pelvic organs (e.g., prostate), and lower limbs, and for cesarean deliveries. Continuous catheter-based epidural infusions of dilute local anesthetics and opioids are used for obstetric labor analgesia and postoperative pain relief after major surgery (e.g., thoracic, abdominal, and less commonly lower limb) to provide analgesia for days if required. Evidence demonstrating that epidural analgesia can reduce pulmonary morbidity and mortality in high-risk patients undergoing major thoracic and abdominal surgery served to propel the practice of epidural analgesia at the beginning of the millennium.[1] Caudal blocks are mostly performed for surgical anesthesia and analgesia in children, and for therapeutic analgesia in adults with chronic pain. Indwelling spinal catheters can be applied long term (from months to years) for the treatment of chronic malignant and nonmalignant pain.

Historical Perspectives

The first case of spinal anesthesia in humans was performed by August Bier in 1898 using the local anesthetic cocaine.[2] Subsequently, spinal anesthesia was successfully performed using procaine by Braun in 1905, tetracaine by Sise in 1935, lidocaine by Gordh in 1949, chloroprocaine by Foldes and McNall in 1952, mepivacaine by Dhunér and

Sternberg in 1961, and bupivacaine by Emblem in 1966. Spinal anesthesia using ropivacaine and levobupivacaine was introduced in the 1980s. The year 1901 marked the first reported use of intrathecal morphine described by Racoviceanu-Pitesti, as well as the first description of caudal anesthesia reported by Cathleen. Lumbar epidural anesthesia in humans was first described by Pagés in 1921, the loss-of-resistance technique by Dogliotti in the 1930s, continuous caudal for obstetrics by Hingson in 1941, and lumbar epidural catheterization for surgery by Curbelo in 1947.[3] The use of epidural morphine analgesia was first reported by Behar in 1979.

Despite the extensive experience using neuraxial techniques throughout the past century, several events caused major setbacks along the way, including the Woolley and Roe case detailing paraplegia after spinal anesthesia in 1954,[4] the reports of persistent neurologic deficits and adhesive arachnoiditis with spinal chloroprocaine in the early 1980s, and cauda equina syndrome with continuous spinal lidocaine anesthesia in the early 1990s.[5] More recently, the potential for catastrophic epidural hematoma with newer potent anticoagulants (e.g., low-molecular-weight heparin [LMWH]) and antiplatelet agents (e.g., clopidogrel) has caused concern.[6]

Anatomy

The spinal cord is continuous with the brainstem proximally and terminates distally in the conus medullaris as the filum terminale (fibrous extension) and the cauda equina (neural extension). This distal termination varies from L3 in infants to the lower border of L1 in adults because of differential growth rates between the bony vertebral canal and the central nervous system.

Surrounding the spinal cord in the bony vertebral column are three membranes (from innermost to outermost): the pia mater, the arachnoid mater, and the dura mater (Fig. 45.1). The cerebrospinal fluid (CSF) resides in the space between the pia mater and the arachnoid mater, termed the *subarachnoid* (or *intrathecal*) *space*. The pia mater is a highly vascular membrane that closely invests the spinal cord and brain. Approximately 500 mL of CSF is formed daily by the choroid plexuses of the cerebral ventricles, with 30 to 80 mL occupying the subarachnoid space from T11 to T12 downward. The arachnoid mater is a delicate, nonvascular membrane that functions as the principal barrier to drugs crossing into (and out of) the CSF and is estimated to account for 90% of the resistance to drug migration.[7] As Liu and McDonald[8] and Bernards[9] emphasize, the functional proof of the arachnoid's role as the primary barrier to flow is the observation that spinal CSF resides in the subarachnoid, and not the subdural, space. The outermost layer is the dura.

Surrounding the dura mater is the epidural space, which extends from the foramen magnum to the sacral hiatus and surrounds the dura mater anteriorly, laterally, and posteriorly. The epidural space is bound anteriorly by the posterior longitudinal ligament, laterally by the pedicles and intervertebral foramina, and posteriorly by the ligamentum flavum. Contents of the epidural space include the nerve roots and fat, areolar tissue, lymphatics, and blood vessels including the well-organized Batson venous plexus.

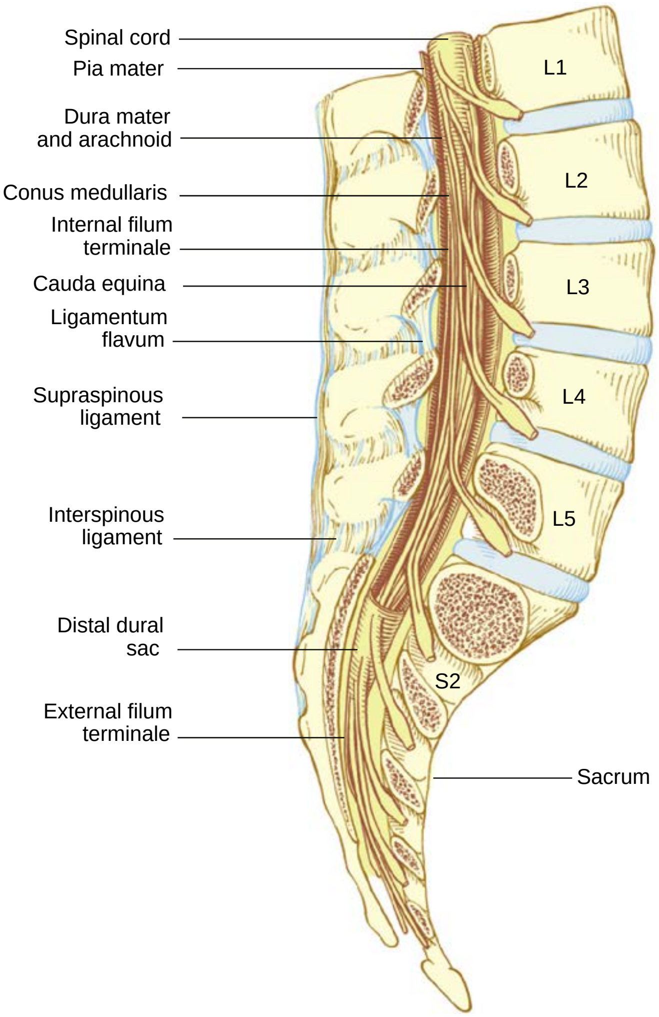

Fig. 45.1 Spinal cord anatomy. Notice the termination of the spinal cord (i.e., conus medullaris) at L1-L2 and termination of the dural sac at S2.

Posterior to the epidural space is the ligamentum flavum (the so-called yellow ligament), which extends from the foramen magnum to the sacral hiatus. Although classically portrayed as a single ligament, it is actually comprised of two ligamenta flava—the right and the left—which join in the middle and form an acute angle with a ventral opening (Fig. 45.2).[10,11] The ligamentum flavum is not uniform from skull to sacrum, nor even within an intervertebral space. Ligament thickness, distance to the dura, and skin-to-dura distance vary with the area of the vertebral canal. The vertebral canal is triangular and largest in area at the lumbar levels, and it is circular and smallest in area at the thoracic levels. The two ligamenta flava are variably joined (fused) in the midline, and this fusion or lack of fusion of the ligamenta flava occurs at different vertebral levels in individual patients.[10] Immediately posterior to the ligamentum flavum are the lamina and spinous processes of vertebral bodies or the interspinous ligaments. Extending from the external occipital protuberance to the coccyx posterior to these structures is the supraspinous ligament, which joins the vertebral spines (see Fig. 45.2).

There are 7 cervical vertebrae, 12 thoracic vertebrae, 5 lumbar vertebrae, and a sacrum. The vertebral arch, spinous process, pedicles, and laminae form the posterior

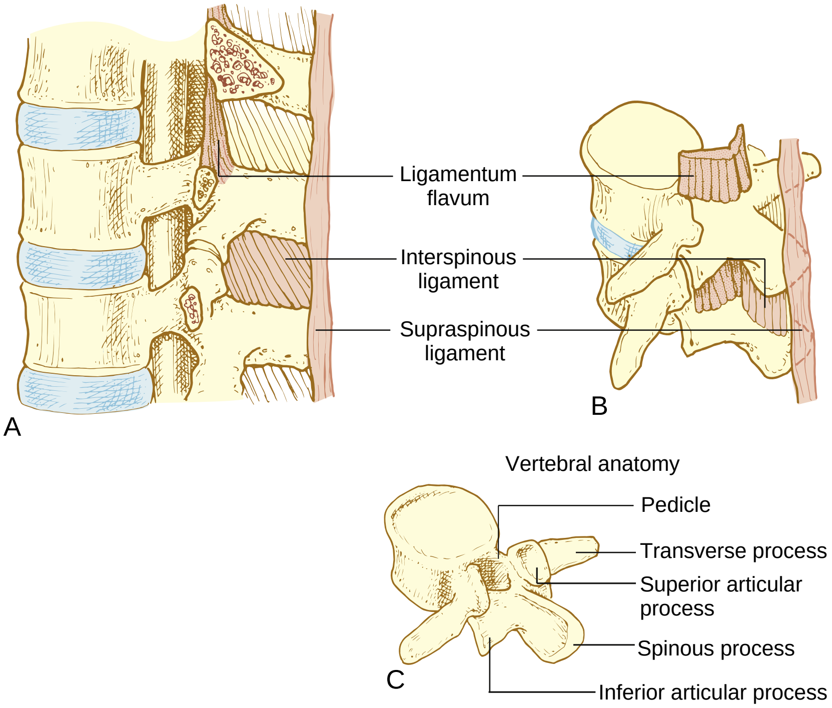

Fig. 45.2 Vertebral anatomy. (A) Sagittal view. (B) Oblique view of the lumbar vertebrae showing the ligamentum flavum thickening in the caudad extent of the intervertebral space and in the midline. (C) Oblique view of a single lumbar vertebra.

elements of the vertebra, and the vertebral body forms the anterior element. The vertebrae are joined together anteriorly by the fibrocartilaginous joints with the central disks containing the nucleus pulposus, and posteriorly by the zygapophyseal (facet) joints. The thoracic spinous process is angulated steeply caudad as opposed to the almost horizontal angulation of the lumbar spinous process. This is a clinically important distinction for needle insertion and advancement in the thoracic versus lumbar levels.

The sacral canal contains the terminal portion of the dural sac, which typically ends at S2. Variation is found in this feature as well, with the termination of the dural sac being lower in children. In addition to the dural sac, the sacral canal contains a venous plexus, which is part of the valveless internal vertebral venous plexus. The volume of the caudal canal in adults, excluding the foramina and dural sac ranges, is about 10 to 27 mL. Perhaps this wide variability in volume accounts for some of the variation in block height with caudal anesthesia (Fig. 45.3).[12]

BLOOD SUPPLY

Blood is supplied to the spinal cord from one anterior spinal artery (originating from the vertebral artery), two posterior spinal arteries (originating from the inferior cerebellar artery), and the segmental spinal arteries (originating from the intercostal and lumbar arteries).[13] The spinal arteries enter the spinal canal at each intervertebral foramen and give off branches to both the nerve roots and the medullary branches to the spinal cord; one of the major branches is the artery of Adamkiewicz, variably entering between T7 and L4 on the left, which supplies the lower thoracic and upper lumbar regions. The anterior two thirds of the spinal cord is supplied by the anterior arterial branches and the posterior one third by the posterior branches. The anterior and deep portion of the cord (gray matter) is most prone to ischemia (leading to anterior horn motor neuron injury, or anterior spinal syndrome) because there are fewer anterior medullary feeder vessels than posterior feeder vessels. Likewise, the midthoracic part of the spinal cord (from T3 to T9) is most at risk where segmental medullary feeder vessels are rare. Venous drainage of the spinal cord follows a similar distribution as the spinal arteries. There are three longitudinal anterior spinal veins and three posterior spinal veins that communicate with the segmental anterior and posterior radicular veins before draining into the internal vertebral venous plexus in the medial and lateral components of the epidural space. There are no veins in the posterior epidural space except those caudal to the L5-S1 disk.

Anatomic Variations

NERVE ROOTS

The spinal nerve roots are not uniform in size and structure. Specifically, Hogan and Toth[14,15] have shown that there is considerable interindividual variability in nerve root size. These differences may help to explain the interpatient differences in neuraxial block quality when equivalent techniques are used on seemingly similar patients. Another anatomic relationship may affect neuraxial blocks; although generally larger than the ventral (motor) roots, the dorsal (sensory) roots are often blocked more easily. This apparent paradox is explained by organization of the dorsal roots into component bundles, which creates a much larger surface area on which the local anesthetics act, possibly explaining why larger sensory nerves are blocked more easily than smaller motor nerves.[8]

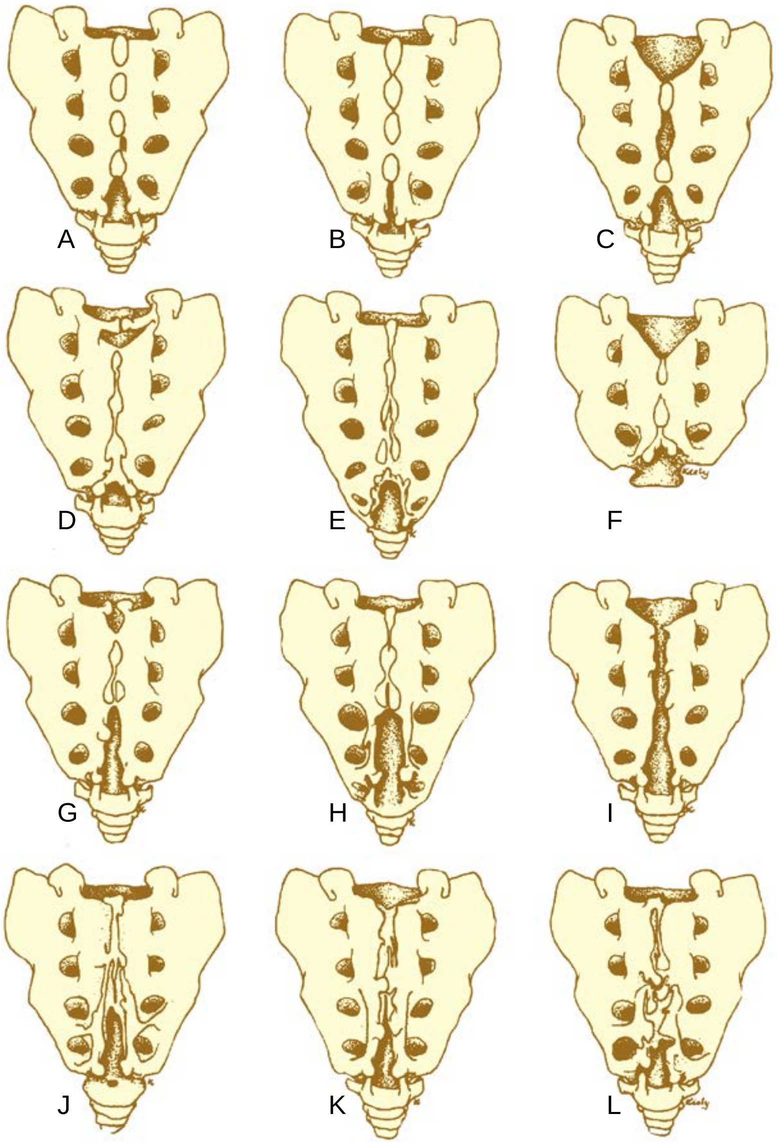

Fig. 45.3 Anatomic variants of the sacrum and sacral hiatus. (A) Normal. (B) Longitudinal slitlike hiatus. (C) Second midline hiatus. (D) Transverse hiatus. (E) Large hiatus with absent cornua. (F) Transverse hiatus with absent coccyx, two prominent cornua, and two proximal "decoy hiatuses lateral to the cornua." (G–I) Large midline defects contiguous with the sacral hiatus. (J–L) Enlarged longitudinal hiatuses, each with an overlying decoy hiatus. (From Willis RJ. Caudal epidural block. In: Cousins MN, Bridenbaugh PO, eds. *Neural blockade in clinical anesthesia and management of pain*. 2nd ed. Philadelphia: JB Lippincott; 1988:365.)

CEREBROSPINAL FLUID

Lumbosacral CSF has a constant pressure of approximately 15 cm H_2O, but its volume varies by patient, in part because of differences in body habitus and weight.[16] It is estimated that CSF volume accounts for 80% of the variability in peak block height and regression of sensory and motor blockade. Nevertheless, except for body weight (less CSF in subjects with high body mass index [BMI]), the volume of CSF does not correlate with other anthropomorphic measurements available clinically.[17] (See section, Factors Affecting Block Height, later in the chapter.)

EPIDURAL SPACE

Hogan's[10] study of frozen cryomicrotome cadaver sections suggests that the epidural space is more segmented and less uniform than previously believed from indirect anatomic analysis. Another study by Hogan[18] has also shown in cadavers that the spread of solution after epidural injection into the tissues of the epidural space is nonuniform, and he postulated that this accounts for the clinical unpredictability of epidural drug spread. This lack of uniformity also extends to age-related differences. There is evidence that adipose tissue in the epidural space diminishes with age,[19] and this decrease in epidural space in adipose tissue may dominate the age-related changes in epidural dose requirements (see Chapter 65).

Mechanism of Action

Local anesthetic binding to nerve tissue disrupts nerve transmission, resulting in neural blockade. For spinal and epidural anesthesia, the target binding sites are located within the spinal cord (superficial and deep portions) and on the spinal nerve roots in the subarachnoid and epidural spaces. The spinal nerve roots and dorsal root ganglia are considered the most important sites of action. Nerves in the subarachnoid space are highly accessible and easily anesthetized, even with a small dose of local anesthetic, compared with the extradural nerves, which are often ensheathed by dura mater (the "dural sleeve"). The speed of neural blockade depends on the size, surface area, and degree of myelination of the nerve fibers exposed to the local anesthetic. Anatomic studies show that the S1 and L5 posterior roots are the largest and thus most resistant to blockade during epidural anesthesia.[15] Smaller nerves are more sensitive to the effects of local anesthetics because of their relatively high membrane surface area to axon unit volume ratio. For example, the small preganglionic sympathetic fibers (B fibers, 1-3 μm, minimally myelinated) are most sensitive to local anesthetic blockade. Among the sensory nerves, the C fibers (0.3-1 μm, unmyelinated), which conduct cold temperature sensation, are blocked more readily or earlier than the A-delta fibers (1-4 μm, myelinated), which conduct pinprick sensation. The A-beta fibers (5-12 μm, myelinated), which conduct touch sensation, are the last to be affected among the sensory fibers. The larger A-alpha motor fibers (12-20 μm, myelinated) are more resistant than any of the sensory fibers. Regression of blockade ("recovery") follows in the reverse order: motor function followed first by touch, then pinprick, and finally cold sensation.[20] Another manifestation of relative sensitivity or susceptibility to the effects of local anesthetics is the observed differences in the peak block height (highest or most cephalad level of anesthesia) according to each sensory modality, which is termed *differential sensory block*. For example, the level of anesthesia to cold sensation (also an approximate level of sympathetic blockade) is most cephalad and is on average one to two spinal segments higher than the level of pinprick anesthesia, which in turn is one to two segments higher than the level of touch anesthesia.[21]

DRUG UPTAKE

When local anesthetic is injected directly into the subarachnoid space during spinal anesthesia, it diffuses through the pia mater and penetrates through the spaces of Virchow-Robin (extensions of the subarachnoid space accompanying the blood vessels that invaginate the spinal cord from the pia mater) to reach the deeper dorsal root ganglia.[22] Furthermore, a portion of the subarachnoid drug diffuses outward through the arachnoid and dura mater to enter the epidural space,[23] whereas some is taken up by the blood vessels of the pia and dura maters.[24]

Drug penetration and uptake is directly proportionate to the drug mass, CSF drug concentration, contact surface area, lipid content (high in spinal cord and myelinated nerves), and local tissue vascular supply, but is inversely related to nerve root size. The concentration of local anesthetic in the CSF is highest at the site of subarachnoid injection in the case of spinal anesthesia (generally L2-L4 levels).

For epidural anesthesia, drug uptake is more complex. Some of the injected local anesthetic will move from the epidural space through the meninges into the CSF to exert its neural blocking effect, whereas some will be lost through vascular absorption into the capillary vessels and into the systemic circulation and uptake into epidural fat. The bioavailability of local anesthetics found in the CSF after epidural administration is low (<20%).

DRUG DISTRIBUTION

Diffusion is the primary mechanism of local anesthetic distribution in the CSF from areas of high concentration (i.e., at the site of injection) toward other segments of the spinal cord with low drug concentration.[25] Rostral spread after the administration of a small local anesthetic dose, often evident within 10 to 20 minutes, is related to the CSF circulation time. Longitudinal oscillations generated by the pulsations of the arteries in the skull are believed to be responsible for CSF bulk flow. This likely facilitates the cephalad distribution of local anesthetic from the lumbar subarachnoid space to the basal cisterns within 1 hour of injection.

Drug distribution in the epidural space is more complex, with possible contributions from one, some, or all of the following mechanisms: (1) crossing the dura mater into the subarachnoid space, (2) rostral and caudal (longitudinal) spread within the epidural space, (3) circumferential spread within the epidural space, (4) exit of the epidural space through the intervertebral foramina, (5) binding to epidural fat, and (6) vascular absorption into the epidural vessels. Longitudinal spread of local anesthetic by bulk flow within the epidural space may occur after the administration of a larger dose (i.e., volume). Factors that may enhance the distribution of local anesthetic within the epidural space are small caliber (greater spread in the thoracic space), increased epidural space compliance, decreased epidural fat content, decreased local anesthetic leakage through the intervertebral foramina (e.g., in the elderly and with spinal stenosis), and increased epidural pressure (e.g., pregnancy).[26] Drug is also preferentially distributed from areas of high to low concentration. Finally, the direction of drug spread varies with the vertebral level—that is, epidural spread is mostly cephalad in the lumbar region, caudad after a high thoracic injection, and spread mostly cephalad after a low thoracic njection.[26]

DRUG ELIMINATION

Regression of neural blockade results from a decline in the CSF drug concentration, which in turn is caused by nonneural tissue uptake and, most importantly, vascular absorption. Time for block regression is also inversely correlated with CSF volume.[27] Drug is absorbed by the vessels in the pia mater or the epidural vessels through back diffusion before entering the systemic circulation. No drug metabolism takes place in the CSF. The rate of elimination is also dependent on the distribution of local anesthetic; greater spread will expose the drug to a larger area for vascular absorption and thus a shorter duration of action. Lipid-soluble local anesthetics (e.g., bupivacaine) bind to epidural fat to form a depot that can slow vascular absorption.

Physiologic Effects

Safe conduct of spinal, epidural, and caudal anesthesia requires an appreciation of their physiologic effects. Neuraxial anesthesia evokes blockade of the sympathetic and somatic (sensory and motor) nervous systems, along with compensatory reflexes and unopposed parasympathetic activity.[28] The physiologic effects of epidural anesthesia are similar to those of spinal anesthesia, with the exception that local anesthetic blood levels reach concentrations sufficient enough to produce systemic effects on their own.

CARDIOVASCULAR

The effects of neuraxial blocks on blood pressure are similar in some ways to the combined use of intravenous α_1- and β-adrenergic blockers on cardiac output: decreased stroke volume and heart rate (see Chapter 14) caused by blockade of the peripheral (T1-L2) and cardiac (T1-T4) sympathetic fibers as well as adrenal medullary secretion. The decrease in arterial blood pressure is believed to be more gradual and of less magnitude with epidural than with spinal anesthesia of comparable sensory block levels. However, when tetracaine (10 mg) spinal anesthesia was compared with lidocaine (20-25 mL of a 1.5% solution) epidural anesthesia, there was a larger decrease in arterial blood pressure (approximately 10%) with the epidural technique than with the spinal anesthetic.[29] Of prime importance, the extent to which arterial blood pressure decreases with either technique depends on multiple factors, including patient age and intravascular volume status.

Stroke Volume

Sympathectomy usually decreases stroke volume. Venous and arterial vasodilation reduces preload (venous return) and afterload (systemic vascular resistance), respectively. Because of the large amount of blood that resides in the venous system (approximately 75% of the total blood volume), the venodilation effect predominates, owing to the limited amount of smooth muscle in venules; in contrast, the vascular smooth muscle on the arterial side of the circulation retains a considerable degree of autonomous tone. Cardiac output is thought to be either maintained or slightly decreased during the onset of spinal anesthesia. Yet a biphasic response, characterized by an early transient increase followed by an eventual decrease in cardiac output,[30] has been observed. This initial increase is caused by a greater magnitude of decline in the systemic vascular resistance than by venous return, especially in elderly patients with preexisting hypertension and high baseline systemic vascular resistance (also see Chapter 65).

The vasodilatory changes after neuraxial blockade that can affect cardiac output depend on each patient's baseline sympathetic tone (i.e., higher sympathetic tone in the elderly equates to a greater hemodynamic change) and the extent of the sympathectomy (i.e., the height of the block). The extent of the sympathectomy is typically described as extending for two to six dermatomes above the sensory block level with spinal anesthesia and at the same level with epidural anesthesia.[31] If normal cardiac output is maintained, systemic vascular resistance should decrease only 15% to 18% after neuraxial blockade in healthy normovolemic patients, even with nearly total sympathectomy. In elderly patients with cardiac disease, systemic vascular resistance may decrease almost 25% after spinal anesthesia, whereas cardiac output decreases only 10%.[32] Determination of baseline autonomic nervous system activity (e.g., blood pressure variability signaled by low-frequency band power and near-infrared spectroscopy reduction) has been found to predict the risk of hypotension in the elderly.[30]

Heart Rate

Heart rate may decrease during a high neuraxial block as a result of blockade of the cardioaccelerator fibers arising from T1 to T4.

Heart rate may also decrease in the presence of extensive peripheral sympathectomy (T5-L2), with venous pooling in the lower extremity and the abdominal and pelvic viscera. Although hypotension will trigger a compensatory baroreceptor sympathetic response (vasoconstriction and increased heart rate) above the level of blockade, the reduction in venous return and right atrial filling causes a decrease in signal output from intrinsic chronotropic stretch receptors located in the right atrium and great veins,[31] leading to a marked increase in parasympathetic activity (vagal tone). The two opposing responses are usually in check with a minimal change in heart rate (or a slight reduction). However, when neuraxial anesthesia is extended to the T1 level, blockade of the cardioaccelerator fibers in addition to a marked reduction in venous return may result in severe bradycardia and even asystole because of unopposed parasympathetic activity. However rare, the likelihood of cardiac arrest appears to be more likely in young, healthy, and conscious patients.[33] The Bezold-Jarisch reflex may be a possible cause of profound bradycardia and circulatory collapse after spinal anesthesia, especially in the presence of hypovolemia, when a small end-systolic left ventricular volume may trigger a mechanoreceptor-mediated bradycardia.[34]

Coronary Blood Flow

When coronary artery blood flow and myocardial metabolism were determined in humans during spinal anesthesia to T4 in hypertensive and normotensive patients, decreases in coronary blood flow (153 to 74 mL/100 g per minute) paralleled the decrease in mean arterial blood pressure (119 to 62 mm Hg), and the percent extraction of myocardial oxygen was unchanged (75% to 72%). Extraction of oxygen was unchanged because myocardial work, as expressed by myocardial use of oxygen, paralleled the decrease in mean arterial blood pressure and coronary blood flow (16 to 7.5 mL/100 g per minute).[35] A high thoracic block in patients with ischemic heart disease can be beneficial, with improvement in global and regional myocardial function and reversal of ischemic changes likely a result of reduced myocardial oxygen demand and left ventricular afterload.[36] Both infarction size and ischemia-induced arrhythmias improved in coronary occlusion experiments in animals, with no apparent vasodilatory effect on the coronary vessels.[37] These data support the observations by Stanley and coworkers[38] but still do not provide a patient-by-patient indication of the organ most at risk for flow-related ischemia.

Treatment

The clinical question of what level of decrease in arterial blood pressure after a neuraxial block is acceptable without a significant decrease in organ perfusion (e.g., brain, liver, gut) remains to be answered, although some human and animal data are available (see respective sections). Once arterial blood pressure decreases to a level at which treatment is believed to be necessary, ephedrine, a mixed adrenergic agonist, provides more appropriate therapy for the noncardiac circulatory sequelae of neuraxial block than does a pure α-adrenergic agonist (see Chapter 14), unless the patient has a specific and defined arterial blood pressure requirement.[39]

That the decrease in arterial blood pressure after neuraxial block can be minimized by the administration of crystalloids intravenously is probably not a valid concept. Specifically, 250- to 2000-mL preblock hydration regimens may temporarily increase preload and cardiac output but do not consistently increase arterial blood pressure or prevent hypotension.[8] Useful techniques to prevent hypotension include the repeated low-dose local anesthetic boluses through a continuous spinal catheter,[40] small-dose unilateral spinal anesthesia, and selective small-dose spinal anesthesia.

CENTRAL NERVOUS SYSTEM

Spinal anesthesia–induced hypotension may decrease regional cerebral blood flow (CBF) in elderly patients and those with preexisting hypertension. In a study of elderly patients who had hypotension during bupivacaine spinal anesthesia, Minville and colleagues demonstrated a significant but transient decrease of middle cerebral artery blood flow velocity and an increase in cerebral vascular resistance, both of which suggest a decrease in cerebral perfusion.[41] There was no change in cognitive function after surgery in any of these patients. Both CBF and velocity decline as a result of changes in the cerebral vasculature, especially in the elderly. Whether cerebral autoregulation is impaired in the elderly is still debatable (see Chapter 65).

Kety and colleagues[42] demonstrated that producing spinal anesthesia to the midthoracic levels with procaine, even in patients with essential hypertension, results in a decrease in mean arterial blood pressure of 26% (155 to 115 mm Hg) accompanied by a 12% (52 to 46 mL/100 g per minute) decrease in CBF. When the level of spinal anesthesia was purposely increased to produce higher levels of block (T4) in normotensive and hypertensive patients, CBF was unchanged in the normotensive group (45-46 mL/100 g per minute), whereas a 19% decrease occurred in the apparently untreated hypertensive patients (46.5-37.5 mL/100 g per minute).[43]

RESPIRATORY

Alterations in pulmonary variables in healthy and even in elderly patients during neuraxial block are usually of little clinical consequence.[44] A decrease in vital capacity follows a reduction in expiratory reserve volume related to paralysis of the abdominal muscles necessary for forced exhalation rather than a decrease in phrenic or diaphragmatic function.[45] Blockade of the intercostal and abdominal muscles during neuraxial anesthesia is adequately compensated by unaltered function of the diaphragm and other accessory respiratory muscles (e.g., sternomastoid, scalenes), especially for forceful inspiration and expiration.[46] Nonetheless, neuraxial block should be used cautiously in the setting of severe respiratory disease because paralysis of the intercostal and abdominal muscles is common. However rare, respiratory arrest associated with spinal anesthesia is often unrelated to phrenic or inspiratory dysfunction but rather to hypoperfusion of the respiratory centers in the brainstem. Supportive evidence for this concept is observed after resuscitation, when apnea almost always disappears as soon as pharmacologic and intravascular fluid therapies have restored cardiac output and arterial blood pressure.

Pregnancy

In young healthy pregnant women undergoing cesarean delivery, spinal bupivacaine, ropivacaine, and levobupivacaine affect pulmonary function minimally (a reduction of 3% to 6% for forced vital capacity and 6% to 13% for peak expiratory flow rate), irrespective of the peak sensory block level.[47] However, in overweight pregnant women, vital capacity declines even more (24% vs. 11%) and recovers more slowly compared with normal-weight pregnant women after hyperbaric spinal bupivacaine administration (see also Chapter 62).[48]

Obesity (also see Chapter 58)

The impact of spinal anesthesia on lung volume variables is significantly reduced compared with general anesthesia[49] but is significantly more in overweight patients than in normal-weight patients.[48] The magnitude of decline in vital capacity is proportional to the BMI value (vital capacity 19% for BMI 30–40 kg/m^2 vs. 33% for BMI >40 kg/m^2).[50] Importantly, however, for obese patients undergoing laparotomy surgery, thoracic epidural anesthesia (TEA) lessens the extent of decline in postoperative vital capacity and hastens recovery when compared with parenterally administered opioids.[49]

GASTROINTESTINAL

Neuraxial blockade from T6 to L1 disrupts splanchnic sympathetic innervation to the gastrointestinal tract, resulting in a contracted gut and hyperperistalsis. Nausea and vomiting may be associated with neuraxial block in as much as 20% of patients and they are primarily related to gastrointestinal hyperperistalsis caused by unopposed parasympathetic (vagal) activity.[51] Atropine is effective in treating nausea associated with high (T5) subarachnoid anesthesia.[52]

TEA has a direct blood pressure–dependent effect on intestinal perfusion.[53] TEA improves anastomotic mucosal blood flow in patients undergoing esophagectomy when mean arterial blood pressure is minimally altered but worsens local perfusion when arterial blood pressure is decreased by about 50%. In colorectal surgery, TEA decreases anastomotic blood flow but improves gastric and transverse colonic blood flow.[54] Correction of systemic hypotension by vasopressor therapy (e.g., norepinephrine) has been found to reverse impaired colonic perfusion. TEA may also reduce the rate of anastomotic leak after emergency laparotomy, esophageal surgery,[55] and other gastrointestinal interventions.[56]

A reduction in hepatic blood flow parallels the reduction in mean systemic arterial pressure in the setting of spinal anesthesia.[57] Although lumbar epidural anesthesia also results in a decline in hepatic perfusion despite colloid preloading in young and elderly patients, hepatic perfusion can increase, though mildly (<10%), with TEA after major abdominal surgery.[57]

RENAL

Despite a predictable decrease in renal blood flow accompanying neuraxial blockade, this decrease is of little physiologic importance.[58,59] One aspect of genitourinary function of clinical importance is the belief that neuraxial blocks are a frequent cause of urinary retention, which delays discharge of outpatients and necessitates bladder catheterization in inpatients (see section Complications–Urinary Retention, later in the chapter). However, this belief is questionable. For example, in orthopedic patients undergoing hip replacement, bladder catheterization was no more frequent after spinal or epidural anesthesia than it was after general anesthesia and opioid analgesics. In any case, excessive volumes of intravenous crystalloid solutions should not be given to patients undergoing spinal anesthesia. The requirement for voiding before discharge in low-risk ambulatory surgery patients after short-acting spinal or epidural anesthetics should be encouraged.[60]

Indications

At the most basic level, neuraxial blockade is indicated when the surgical procedure can be accomplished with a sensory level of anesthesia that does not produce adverse patient outcomes. The level of anesthesia or analgesia required is of prime importance because the physiologic effects of a high-level block may be untenable.

NEURAXIAL ANESTHESIA

When considering neuraxial anesthesia, the nature and duration of surgery, patient comorbidities, the ease of spinal insertion (i.e., positioning and spinal pathology), and the relative benefits and risks to the individual are important. Spinal anesthesia is most commonly used for patients who require surgical anesthesia for procedures of known duration that involve the lower extremities, perineum, pelvic girdle, or lower abdomen. Descriptions of spinal anesthesia as the primary surgical anesthetic have more recently expanded to include lumbar spine surgery,[61] as well as upper abdominal procedures, such as laparoscopic cholecystectomy.[62] Spinal anesthesia may be useful when patients wish to remain conscious or when comorbidities such as severe respiratory disease or a difficult airway increase the risks of using general anesthesia. Epidural anesthesia can also be used for the lower extremities, perineum, pelvic girdle, or lower abdomen, but by virtue of intermittent or continuous catheter-based local anesthetic delivery, the duration of surgical anesthesia is not necessarily finite as it is with single-injection spinal anesthesia. Continuous catheter-based spinal anesthesia is both less conventional and less commonly used than either single-shot spinal anesthesia or catheter-based epidural anesthesia, but may be especially useful when insertion of an epidural catheter is challenging[63] or in the setting of severe cardiac disease when the reliability of a single-shot spinal anesthetic must be combined with more hemodynamically stable incremental dosing.

NEURAXIAL ANALGESIA

Local anesthetics (as well as other additives, discussed later) applied to the neuraxis in subanesthetic doses can provide potent, long-lasting analgesia for a variety of indications, including intraoperative analgesia, acute postsurgical pain,[64] and severe chronic pain associated with malignancy. The use of intrathecal and/or epidural opioids either alone or in combination with local anesthetics can provide excellent quality pain relief[65,66,66a] and are an analgesic mainstay in labor and delivery,[67,68] during and after hip[69] or knee replacement,[70] in laparotomy,[71] in thoracotomy,[72] and increasingly even in cardiac surgery.[73,74] Some of the most important benefits of epidural analgesia are realized in patients with preexisting respiratory disease undergoing abdominal surgery.[75] Neuraxial analgesia may have other beneficial outcomes beyond analgesia and these are reviewed later.

Contraindications

ABSOLUTE

There are few absolute contraindications to neuraxial blockade. Some of the most important include patient refusal, localized sepsis, and an allergy to any of the drugs planned for administration. A patient's inability to maintain stillness during needle puncture, which can expose the neural structures to traumatic injury,[76] as well as raised intracranial pressure, which may theoretically predispose to brainstem herniation,[77] should also be considered absolute contraindications to a neuraxial technique.

RELATIVE

Relative contraindications must be weighed against the potential benefits of neuraxial blockade. Relative contraindications can be approached by system.

Neurologic

Myelopathy or Peripheral Neuropathy. A preexisting neurologic deficit can in theory worsen the extent of any injury in this group of patients (so-called double-crush phenomenon). While many reports suggest central neuraxial techniques may be used safely, there is no definitive evidence.[76,78-80] Chronic low back pain without neurologic deficit is not a contraindication to neuraxial blockade. The association between neuraxial techniques and the exacerbation of back pain symptoms is not documented.

Spinal Stenosis. Patients with spinal stenosis appear to be at increased risk of neurologic complications after neuraxial blockade,[81] but the relative contribution of surgical factors and natural history of the spinal pathology itself is unknown. Using a lower mass of local anesthetic may in theory reduce the risk if spinal anesthesia is undertaken in the setting of spinal stenosis.

Spine Surgery. Previous spine surgery does not predispose patients to an increased risk of neurologic complications after neuraxial blockade.[81,82] However, depending on postsurgical anatomy and the presence of scar tissue, adhesions, hardware, and/or bone grafts, needle access to the CSF, or epidural space and/or epidural catheter insertion may be challenging or impossible. In addition, the resultant spread of local anesthetic in the CSF or epidural space can be unpredictable and incomplete.

Multiple Sclerosis. Patients with multiple sclerosis (MS) may be more sensitive to neuraxial local anesthetics and thus exhibit a prolonged duration of motor and sensory blockade; however, any association between neuraxial anesthesia and exacerbation of MS symptoms is not based in evidence.[83,84] Given that demyelinated fibers may be more prone to the toxic effects of local anesthetics, it is prudent to use a lower dose and concentration of spinal local anesthetic in this group of patients, or else consider epidural rather than spinal anesthesia.

Spina Bifida. Spina bifida comprises a wide spectrum of congenital spinal cord malformations. Depending on the severity of the neural tube defect, patients with spina bifida may have a tethered cord and the ligamentum flavum may be absent, thereby increasing the potential for traumatic needle injury to the spinal cord. In patients who have undergone repair of open spinal dysraphisms, the spread of local anesthetic in the CSF and epidural space (if present) can be highly variable. Neuraxial techniques have been successfully used in isolated spina bifida occulta patients, but are not advised in the setting of severe neural tube defects such as diastematomyelia or tethered cord.

If, after consideration of risks and benefits, a neuraxial technique is to be undertaken in a patient with a neural tube defect, a careful clinical and radiologic evaluation of neurologic status must first be undertaken and noted along with documentation of the discussion of the risks and benefits.

Cardiac (also see Chapter 54)

Aortic Stenosis or Fixed Cardiac Output. The unpredictable speed and extent to which systemic vascular resistance is reduced after spinal anesthesia may cause many providers to avoid spinal anesthesia in preload-dependent patients and try to prevent a dangerous decrease in coronary perfusion. This concern is borne of theoretic risk and a great deal of caution rather than evidence.[85] Clinical practice mandates that neuraxial anesthesia be considered individually for each patient with aortic stenosis in the context of their own disease severity, left ventricular function, and case urgency. A catheter-based neuraxial anesthetic, whether it is an epidural or intrathecal catheter, allows for the repeated administration of small doses of local anesthetic, with potentially more control over hemodynamic changes, and may be a logical alternative choice.

Hypovolemia. An extension of patients who are preload-dependent, hypovolemic patients may exhibit an exaggerated hypotensive response to the vasodilatory effects of neuraxial blockade.

Hematologic

Thromboprophylaxis. Borne of the catastrophic cases of spinal hematoma causing paralysis associated with the introduction and use of LMWH in the United States (US FDA public health advisory: reports of epidural or spinal hematomas with the concurrent use of low molecular weight heparin and spinal/epidural anesthesia or spinal puncture. US Department of Health and Human Resources, 1997), the American Society of Regional Anesthesia and Pain Medicine (ASRA) first published a practice advisory to guide the provision of neuraxial techniques in patients receiving antithrombotic or thrombolytic therapy in 2004. Now in its fourth iteration and addressing a myriad of novel potent oral anticoagulants, the ASRA practice advisory[6] is an invaluable resource for providers performing neuraxial techniques in this challenging and ever-growing patient population. A summary of the ASRA guidelines[1] is reproduced in Table 45.1.

Inherited Coagulopathy. The safety of neuraxial techniques in patients with common bleeding diatheses is not well documented. Hemorrhagic complications after neuraxial techniques in patients with known hemophilia, von Willebrand disease, or idiopathic thrombocytopenic purpura appear infrequently when factor levels are more than 0.5 IU/mL for factor VIII, von Willebrand factor, and ristocetin cofactor activity, or when the platelet count is greater than 50×10^9/L[1] before block performance.[86] The minimum safe factor levels and platelet count for neuraxial blockade, however, remain undefined in both the obstetric and general populations.[86]

Infection

Theoretic concerns based on animal data and laboratory and case reports in humans[87-89] suggest iatrogenic seeding of the neuraxis in the setting of a systemic infection. Some providers avoid neuraxial techniques in febrile patients. A definitive causative relationship between existing systemic infection and meningitis or epidural abscess after a neuraxial technique has never been shown. In fact, a lumbar puncture is a critical component of the investigation of fever of unknown origin, yet there are no definitive data linking lumbar puncture to increased risk of neuraxial infection in this setting.[90] Although the profound vasodilation may be sufficient reason to avoid neuraxial techniques in patients with profound bacteremia or septic shock, the theoretic risk of seeding the intrathecal or epidural spaces by performing neuraxial techniques in patients with untreated systemic infection further supports using another technique. Yet patients with evidence of systematic infection may safely undergo neuraxial anesthesia once antibiotic therapy has been initiated and the patient has demonstrated a response to the antibiotics.[90]

Spinal Anesthesia

FACTORS AFFECTING BLOCK HEIGHT

The dermatomal level required for various surgical procedures is outlined in Table 45.2. The provider must recall that intraabdominal structures such as the peritoneum (T4), bladder (T10), and uterus (T10) have a spinal segment innervation that may be much more cephalad compared with that of the corresponding skin incision used to operate on these structures.

Drug, patient, and procedural factors can all affect the distribution of local anesthetic spread within the intrathecal space, some of which are more clinically relevant than others.[25,91] Many of these factors are not controllable by the anesthesiologist, leading to significant interpatient variability (Table 45.3).

TABLE 45.1 ASRA Evidence-Based Guidelines for Neuraxial Anesthesia in the Patient Receiving Thromboprophylaxis

DRUG	NEURAXIAL NEEDLE/CATHETER PLACEMENT			NEURAXIAL CATHETER REMOVAL		COMMENTS
	Discontinuation prior to placement	**Restart following needle placement**	**Indwelling catheter placement**	**Discontinuation prior to removal**	**Restart following removal**	
Antiplatelet agents						
Aspirin	*Safe for all categories*					
NSAIDs	*Safe for all categories but caution with concomitant drugs that may affect coagulation*					
Clopidogrel	5-7 d	Immediately *If loading dose*: 6 h	Catheters may be maintained for 1-2 days after restarting Clopidogrel or Ticlodipine		Immediately *If loading dose*: 6 h	
Ticlodipine	10 d					
Prasugrel	7-10 d		Avoid catheters			
Ticagrelor	5-7 d					
Dipyridamole	24 h	6 h	Avoid catheters		6 h	
GP IIa/IIIb inhibitors Abciximab Eptifibatide Tirofiban	*Avoid until platelet function returns to normal*	*These drugs are generally contraindicated for 4 weeks post surgery*				
Unfractionated Heparin						
Intravenous	4-6 h and confirm normal coagulation	1 h	Safe	4-6 h and confirm normal coagulation	1 h	*Check platelet count before needle placement or catheter removal if duration of LMWH > 4 d*
Subcutaneous						
Low-dose prophylaxis	4-6 h or confirm normal coagulation		Safe	4-6 h and confirm normal coagulation		*5,000 U SC bid or tid*
Higher-dose prophylaxis	12 h and confirm normal coagulation	1 h	Safety of catheters not established		1 h	*7,500-10,000 U SC bid or ≤20,000 U/d*
Therapeutic	24 h and confirm normal coagulation		Avoid catheters			*>10,000 U SC/dose or >20,000 U/d*
Low molecular weight heparin						
Once daily prophylaxis	12 h	12 h	Safe	12 h	4 h	*Check platelet count before needle placement or catheter removal if duration of LMWH > 4 d*
Twice daily prophylaxis			Avoid catheters			
Therapeutic dose	24 h	24 - 72 h	Avoid catheters			
Oral anticoagulants						
Coumarins	Ideally 5 d and INR <1.5	No delay	Monitor INR daily and check sensory/motor function routinely	INR < 1.5	No delay	
Apixaban	72 h	6 h	Avoid catheters		6 h	*Refer to ASRA guidelines if unanticipated indwelling catheter*
Rivaroxaban		6 h				

Abbreviations: bid=twice a day, tid=three times a day, d=day(s), h=hour(s), SC=subcutaneous, U=unit(s). *Reg Anes Pain Med* 2018; 43: 263-309.

Drug Factors

The adjustable factors for any given local anesthetic solution are dose, volume, concentration, temperature, and baricity. Baricity and dose are most important.

Baricity. Baricity is the ratio of the density of a local anesthetic solution to the density of CSF. Density is defined as the mass per unit volume of solution (g/mL) at a specific temperature. Density may be compared between different substances by calculating the specific gravity, which is the ratio of the density of a solution to the density of water. Because density varies inversely with temperature, the baricity of a local anesthetic solution is conventionally defined at 37°C. The density of CSF is 1.00059 g/L.[92] Local anesthetic solutions that have the same density as CSF are termed *isobaric*, those that have a higher density than CSF are termed *hyperbaric*, and those with a lower density than CSF are termed *hypobaric*. The spread of hyperbaric solutions is more predictable,[93] with less interpatient variability.[94] To make a drug hyperbaric to CSF, it must be denser than CSF, with a baricity appreciably more than 1.0000 or a density appreciably more than 1.00059. The reverse is true for making a drug hypobaric to the CSF. Dextrose and sterile water are commonly added to render local anesthetic solutions either hyperbaric or hypobaric, respectively. The clinical importance of baricity is the ability to influence the distribution of local anesthetic spread based on gravity. Hyperbaric solutions will preferentially spread to the dependent regions of the spinal canal, whereas hypobaric solutions will spread to nondependent regions. Isobaric solutions tend not to be influenced by gravitational forces.[95] Anesthesiologists can capitalize on this phenomenon by altering the position of the patient. For example, the administration of hyperbaric local anesthetic to patients in the lateral decubitus position will result in a preferential anesthetic effect on the dependent side, whereas the opposite is true for the administration of a hypobaric solution. A thoughtful understanding of the natural curvatures of the vertebral column can help predict local anesthetic spread in patients placed in the horizontal supine position immediately after intrathecal administration. Hyperbaric local anesthetics injected, while sitting, at the L3-L4 or L4-L5 interspace will spread with gravity from the height of the lumbar lordosis down toward the trough of the thoracic kyphosis in the horizontal supine position, resulting in a higher level of anesthetic effect than isobaric or hypobaric solutions.[91] Hyperbaric solutions are also useful in small doses for a saddle block and to achieve unilateral anesthesia. CSF and local anesthetic density change with temperature. Plain bupivacaine 0.5%, for example, may be isobaric at 24°C but is slightly hypobaric at 37°C. A small volume of drug at room temperature injected intrathecally quickly equilibrates after injection and increases to the temperature of the CSF. Nevertheless, increasing temperature decreases density of a solution and warming of local anesthetic solution to body temperature, therefore making it more hypobaric, increases the block height in patients who remain seated for several minutes after injection.[96]

TABLE 45.2 Dermatomal Level Required for Various Common Surgical Procedures

Type of Surgery	Dermatomal Level
Upper abdominal surgery	T4
Cesarean delivery	T4
Transurethral resection of prostate	T10
Hip surgery	T10
Foot and ankle surgery	L2

Dose, Volume, and Concentration. The dose, volume, and concentration are inextricably linked (Volume × Concentration = Dose), but dose is the most reliable determinant of local anesthetic spread (and thus block height) when compared with either volume or concentration for isobaric and hypobaric local anesthetic solutions.[97,98] Hyperbaric local anesthetic injections are primarily influenced by baricity.

The choice of local anesthetic itself does not influence spread if all other factors are controlled. Additive drugs, other than opioids, also do not affect spread. However, opioids do seem to increase mean spread,[91,99] possibly as a result of pharmacologic enhancement at the extremes of the spread where the local anesthetic block alone would have been subclinical.[100,101]

TABLE 45.3 Factors Affecting Local Anesthetic Distribution and Block Height

	More Important	Less Important	Not Important
Drug factors	Dose Baricity	Volume Concentration Temperature of injection Viscosity	Additives other than opioids
Patient factors	CSF volume Advanced age Pregnancy	Weight Height Spinal anatomy Intraabdominal pressure	Menopause Gender
Procedure factors	Patient position Epidural injection post spinal	Level of injection (hypobaric more than hyperbaric) Fluid currents Needle orifice direction Needle type	

CSF, Cerebrospinal fluid. Modified from Greene NM. Distribution of local anesthetic solutions within the subarachnoid space. *Anesth Analg*. 1985;64(7):715–730.

Patient Factors

Patient characteristics that may influence block height include patient height, weight, age, sex, pregnancy, anatomic configuration of the spine, and the CSF properties (volume and composition). Within the range of "normal-sized" adults, patient height does not seem to affect the spread of spinal anesthesia. This is likely because the length of the lower limb bones rather than the vertebral column contributes most to adult height. A correlation has been found between the vertebral column length and local anesthetic spread[102] and, at extremes of height, consideration should be given to altering the dose accordingly.

The CSF volume is an important patient-related factor that significantly influences peak block height and regression of sensory and motor blockade.[17] Lumbosacral CSF has a fairly constant pressure of approximately 15 cm H_2O but its volume varies from patient to patient, in part because of differences in body habitus and weight.[16] In a small sample of patients, block height varied indirectly with CSF volume.[17] Unfortunately, CSF volume does not correlate well with anthropomorphic measurements available clinically other than body weight.[17] In theory, the increased abdominal mass in obese patients, and possible increased epidural fat, may decrease the CSF volume and therefore increase the spread of local anesthetic and block height. This has indeed been demonstrated using hypobaric solutions,[103,104] which are characterized by more variable spread anyway, but not hyperbaric solutions (see Chapter 58).[103,105]

CSF density can also vary between and within individuals depending on sex, menopausal status, and pregnancy (see Chapter 62).[92] The density of CSF is lower in women compared with men, premenopausal compared with postmenopausal women, and pregnant compared with nonpregnant women. Although this may affect relative baricity of local anesthetics, the clinical variation in spread is probably unimportant.

Advanced age is associated with increased block height (see Chapter 65).[106,107] In older patients, CSF volume decreases, whereas its specific gravity increases. Further, the nerve roots appear more sensitive to local anesthetic in the aged population.

Gender can theoretically affect block height by several mechanisms. CSF density is higher in males, thereby reducing the baricity of local anesthetic solution and possibly limiting the extent of cephalad spread. In the lateral position, the broader shoulders of males relative to their hips make the lateral position slightly more head-up. The reverse is true in females who have a slightly head-down tilt in the lateral position compared with males. Despite this, there is little objective data that males have a slightly less cephalad spread than females in the lateral position.

Variations of the spine may be an important contributor to block height. Scoliosis, although it possibly makes insertion of the needle more difficult, will have little effect on local anesthetic spread if the patient is turned supine. Kyphosis, however, in a supine patient may affect the spread of a hyperbaric solution. Spread of local anesthetic is enhanced by changes in the lumbar lordosis during pregnancy, as well as by the volume and density of CSF, by twin pregnancies compared with singletons, by intraabdominal pressure increases (possibly), and by a progesterone-mediated increase in neuronal sensitivity.

Procedure Factors

Patient position, needle type and alignment, and the level of injection are each procedure-related factors that can affect block height. Combined with the baricity and local anesthetic dose, patient position is the most important factor in determining the block height. Position should not affect the spread of a truly isobaric solution.[95] Intrathecal local anesthetic appears to stop spreading 20 to 25 minutes after injection, thus positioning of the patient is most important during this time period, but particularly in the initial few minutes. However, marked changes in patient posture up to two hours after injection can still result in significant changes in the block level, probably because of bulk movement of CSF.[108,109] Although a 10-degree head-up tilt can reduce the spread of hyperbaric solutions without hemodynamic compromise,[110] a head-down tilt does not always increase the spread of hyperbaric bupivacaine.[111] Flexion of the hips in combination with the Trendelenburg position flattens the lumbar lordosis and has been shown to increase cephalad spread of hyperbaric solutions.[112] A "saddle block" where only the sacral nerve roots are anesthetized can be achieved by using a small dose of hyperbaric local anesthetic while the patient remains in the sitting position for up to 30 minutes. When larger hyperbaric doses are administered, however, the block can still extend cephalad despite maintaining the sitting position for a prolonged period of time.[113] The reverse holds true for hypobaric solutions, where block height is greater (than hyperbaric solutions) if they are administered in a sitting position.[114]

The specific needle type and orientation of the orifice may affect block quality. With hypobaric solutions, cephalad alignment of the orifice of Whitacre, but not Sprotte, needles produces greater spread.[115-117] The orientation of the needle orifice does not appear to affect the spread of hyperbaric solutions. When directing the needle orifice to one side (and using hyperbaric anesthetic), a more marked unilateral block is achieved again when using a Whitacre, rather than a Quincke, needle.[118]

The level of injection affects block height. Most studies have demonstrated that, even when the difference is only one interspace more cephalad, the block height is greater[119-122] when using isobaric bupivacaine. The level of injection does not appear to influence the spread of hyperbaric solutions.[123,124] Injection rate and barbotage (repeated aspiration and reinjection of CSF) of isobaric and hyperbaric solutions have not consistently been shown to affect block height.[91] A slower injection may actually increase spread, and this is perhaps also safer because forceful injection may cause the syringe to disconnect from the needle. Other maneuvers that do not appear to affect block height are coughing and straining after local anesthetic injection. This is related to the physics of injecting drugs into a closed column of CSF, which instantaneously transmits pressure changes throughout the CSF column, such as those that occur with coughing or straining.[25] The injection of local anesthetic or even saline into the epidural space after a spinal anesthetic increases the block height. This is discussed separately in the combined spinal-epidural (CSE) section.

DURATION

The duration of a spinal anesthetic depends on how this variable is defined. For example, the duration of surgical anesthesia is less than the time for complete block resolution. In addition, surgical anesthesia depends on the surgical site because anesthesia is more prolonged at the lower lumbar and sacral levels than at those more cephalad from where the block regresses first. Duration is affected primarily by the dose,[97,125] the intrinsic properties of the local anesthetic (which affect elimination from the subarachnoid space), and the use of additives (if applicable). The latter two are described later. Hyperbaric solutions have a shorter duration of action than isobaric solutions.[125]

PHARMACOLOGY

The clinical effects of intrathecal local anesthetics are mediated by drug uptake and distribution within the CSF and elimination. These in turn are dictated in part by the p*K*a, lipid solubility, and protein binding of the local anesthetic solution. Rather than their pharmacologic structure (i.e., amide or ester), it is the duration of action—short-acting (i.e., procaine, chloroprocaine, articaine), intermediate-acting (i.e., lidocaine, prilocaine, mepivacaine), and long-acting (i.e., tetracaine, bupivacaine, levobupivacaine, ropivacaine)—that is most often used to classify local anesthetics in the clinical setting. The choice and dose of local anesthetic depend on both the expected duration and the nature (location, ambulatory) of surgery. Table 45.4 shows a range of local anesthetics used for spinal anesthesia with corresponding doses, onset times, and durations of action.[126-134]

Short- and Intermediate-Acting Local Anesthetics

Procaine. Procaine is a short-acting ester local anesthetic and one of the oldest spinal anesthetics, having originally replaced cocaine as the drug of choice for spinal anesthesia in the early 20th century. Procaine itself was then replaced by lidocaine, but with concerns about lidocaine and transient neurologic symptoms (TNS), procaine has recently been reexamined as an alternative fast-acting local anesthetic. However, it is not commonly used because of a more frequent failure rate than lidocaine, significantly more nausea, and a slower time to recovery.[135] If used, it is often administered as a hyperbaric drug in a dose ranging between 50 and 200 mg in a 10% concentration.

Chloroprocaine. Chloroprocaine is an ultra–short-acting ester local anesthetic that was introduced in the 1950s. Its initial popularity stemmed from its rapid metabolism by pseudocholinesterase, which translated into minimal systemic or fetal effects in the setting of epidural labor analgesia. However, its reputation as a spinal anesthetic has been tarnished because of reports of neurologic injury associated with the preservative once used in older preparations of the drug (see Complications, discussed later).[136-139] Recently, interest in chloroprocaine has increased for use in spinal anesthesia for ambulatory surgery (see Chapter 72). Modern, preservative-free preparations of chloroprocaine administered in small doses (30-60 mg) produce reliable, short-duration spinal anesthesia,[126] with a faster recovery time than procaine, lidocaine, and bupivacaine.[140-144] TNS can occur with modern chloroprocaine preparations, albeit at a considerably lesser rate (0.6%) than lidocaine (14%).[145-147]

Articaine. Articaine is a relatively novel amide local anesthetic that also has an ester linkage. The ester linkage allows for metabolism by nonspecific cholinesterases. It has been widely used since 1973 for dental nerve blocks with a good safety profile. Intrathecal articaine has not been extensively investigated, but studies do suggest that doses of 50 to 80 mg with or without glucose appear to provide rapid-onset spinal anesthesia for about 1 hour, with a recovery profile faster than bupivacaine.[148,149]

Lidocaine. Lidocaine is a hydrophilic, relatively poorly protein-bound amide local anesthetic. It has a rapid onset

TABLE 45.4 Dose, Block Height, Onset Times, and Duration of Commonly Used Spinal Anesthetics

	DOSE (MG)		DURATION (MIN)		
Local Anesthetic Mixture	**To T10**	**To T4**	**Plain**	**Epinephrine (0.2 mg)**	**Onset (min)**
Lidocaine 5% (with/without dextrose)[*]	40-75	75-100	60-150[†]	20%-50%	3-5
Mepivacaine 1.5% (no dextrose)	30-45[‡]	60-80[§]	120-180[¶¶]	—	2-4
Chloroprocaine 3% (with/without dextrose)	30-40	40-60	40-90[¶]	N/R	2-4
Bupivacaine 0.5%-0.75% (no dextrose)	10-15	12-20	130-230[#]	20%-50%	4-8
Levobupivacaine 0.5% (no dextrose)	10-15	12-20	140-230[#]	—	4-8
Ropivacaine 0.5%-1% (with/without dextrose)	12-18	18-25	80-210[**]	—	3-8

[*] Lidocaine is not commonly used now.

[§] Median peak block height in this study with 60 mg was T5, not T4.

[¶¶] Regression to S1 for block duration.

[¶] Regression to L1.

[#] Regression to L2.

[**] Regression to S2.

N/R, Not recommended. Note that duration depends on how the regression of the block is measured, which varies widely between studies.

and intermediate duration and is used in doses of 50 to 100 mg for shorter procedures that can be completed in 1.5 hours or less. It was traditionally prepared as a 5% solution in 7.5% dextrose; this preparation has been associated with both permanent nerve injury and TNS (see section Complications, discussed later). Despite efforts to reduce the concentration of both the drug and dextrose,[150,151] the use of intrathecal lidocaine declined and has not yet recovered.

Prilocaine. Prilocaine is an amide local anesthetic based on the structure of lidocaine. Prilocaine was introduced in 1965 and has an intermediate duration of action that may lend itself to use in the ambulatory surgery setting.[152] A dose of 40 to 60 mg of 2% hyperbaric prilocaine can provide a block to T10 for 100 to 130 minutes, whereas as little as 20 mg combined with fentanyl has been successfully used for ambulatory arthroscopic knee surgery.[153] Prilocaine is rarely associated with TNS.[152,154,155] In large doses (>600 mg), prilocaine can result in methemoglobinemia. This should not be an issue with doses used for spinal anesthesia, but it has been reported after epidural infusions.[156]

Mepivacaine. Mepivacaine is another short-acting amide local anesthetic. It was first introduced for spinal anesthesia in 1962 and was initially prepared as a hyperbaric solution. The use of spinal mepivacaine has declined because the incidence of TNS after hyperbaric mepivacaine was similar to that of lidocaine,[147] although TNS were less frequent with the isobaric preparation of mepivacaine.[157-159] Doses of 30 to 80 mg with and without additives have been used (see Table 45.4) and, when compared with lidocaine, mepivacaine has a slightly longer duration of action.[160]

Long-Acting Local Anesthetics

Tetracaine. Tetracaine is an ester local anesthetic with a rate of metabolism one tenth that of chloroprocaine. It is packaged either as Niphanoid crystals (20 mg) or as an isobaric 1% solution (2 mL, 20 mg). When Niphanoid crystals are used, a 1% solution is obtained by adding 2 mL of preservative-free sterile water to the crystals. Mixing 1% solution with 10% dextrose produces a 0.5% hyperbaric preparation that may be used for perineal and abdominal surgery in doses of 5 and 15 mg, respectively. Tetracaine is usually combined with a vasoconstrictor additive because the duration of tetracaine alone can be unreliable. Although such combinations can provide up to 5 hours of anesthesia,[161-164] the addition of phenylephrine in particular has been associated with TNS.[165]

Bupivacaine. Bupivacaine was introduced in 1963 and is a highly protein-bound amide local anesthetic with a slow onset because of its relatively high p*K*a. It is appropriate for procedures lasting up to 2.5 to 3 hours (see Table 45.4).[166,167] Bupivacaine is available as 0.25%, 0.5%, and 0.75% clear isobaric solutions and also as a hyperbaric 0.5% (in Europe) and 0.75% solution containing 80 mg/mL glucose. At room temperature, plain bupivacaine is actually slightly hypobaric compared with CSF. Recovery profiles using small doses appear to be similar to that of lidocaine[168-170] and thus low-dose bupivacaine is used in ambulatory procedures. A recent systematic review[171] concluded that 4 to 5 mg of hyperbaric bupivacaine combined with unilateral positioning was adequate for short knee arthroscopy procedures. Bupivacaine is rarely associated with TNS.

Levobupivacaine. Levobupivacaine is the pure S (−) enantiomer of racemic bupivacaine. Although it is used in similar doses to bupivacaine and has a similar onset and duration, levobupivacaine potency appears to be slightly less than bupivacaine.[129] Nevertheless, the majority of clinical studies using identical doses of levobupivacaine and bupivacaine have found no significant difference in clinical efficacy for spinal anesthesia.[129,172-174] The main advantage of levobupivacaine is that it is less cardiotoxic than bupivacaine,[175,176,178] which is more of a theoretic than a real risk in the setting of spinal anesthesia.

Ropivacaine. Ropivacaine was introduced in 1996 and is another highly protein-bound amide local anesthetic. It is structurally related to bupivacaine, with the same p*K*a (8.1) and so it is also characterized by slow onset and a long duration of action. Compared to bupivacaine, the proposed advantages of spinal ropivacaine were less cardiotoxicity and greater motor-sensory block differentiation, resulting in less motor block. Subsequently, the potency of ropivacaine was found to be 0.6 that of bupivacaine.[179-181] When ropivacaine is given in an equivalent dose to bupivacaine, there is slightly less motor block and earlier recovery with ropivacaine.[8,182-184]

Spinal Additives

Whether administered into the CSF in conjunction with a local anesthetic or alone, a variety of medications may exert a direct analgesic effect on the spinal cord and nerve roots, or prolong the duration of sensory and motor blockade. As such, the coadministration of these agents often allows for a reduction in the required dose of local anesthetic, with the advantage of motor block sparing and faster recovery while still producing the same degree of analgesia.

Opioids. The effects of opioids within the CSF are complex, because of a combination of direct spinal cord dorsal horn opioid receptor activation, cerebral opioid receptor activation after CSF transport, and peripheral and central systemic effects after vascular uptake. The effect at each of these sites depends on both the dose administered and the physicochemical properties of the opioid, particularly lipid solubility. Highly lipid-soluble drugs such as fentanyl and sufentanil have a more rapid onset and shorter duration of action than more hydrophilic opioids. In addition to increasing uptake into neural tissue, greater lipid solubility results in rapid uptake into both blood vessels (with a resultant systemic effect) and fatty tissue. The spread of lipophilic opioids within the CSF is therefore more limited than hydrophilic opioids such as morphine, which demonstrate greater spread as a result of slower uptake and elimination from the CSF. As a result, hydrophilic opioids have a greater risk of late respiratory depression, which is one of the rare but most serious consequences of intrathecal opioid administration. The extent of neural tissue and vascular uptake also affects the potency of intrathecal opioids. For example, the relative intrathecal to intravenous potency of morphine is 200 to 300 to 1, whereas for fentanyl and sufentanil it is only 10 to 20 to 1.[185] In addition to respiratory depression, intrathecal opioids have other side effects including nausea and vomiting, pruritus, and urinary retention. These are discussed later in the Complications section.

Hydrophilic Opioids. Preservative-free morphine is the most widely used hydrophilic opioid in spinal anesthesia. It has a slow onset but provides analgesia for up to 24 hours.[186] Adequate analgesia is achieved with 100 µg, with minimal side effects for cesarean deliveries, whereas the most efficacious dose for major orthopedic surgery is less clear.[187] Doses as high as 1000 µg may be used for major abdominal surgery or thoracotomies, where it is becoming increasingly common to administer spinal opioids alone as a simple alternative to epidural local anesthetic–based analgesia. The magnitude of the analgesic response and the optimal dose remain unclear. Given adverse effects increase at higher doses it has been suggested that the lowest effective dose (<300 microg) should be used.[66a] Overall, the beneficial effects of intrathecal morphine seem most marked in abdominal surgery, and within the first 24 hours in particular.[186,188]

Diamorphine is available for use in the United Kingdom only. It is a lipid-soluble prodrug that crosses the dura faster than morphine and is cleared from the CSF more quickly than morphine. Once in the dorsal horn of the spinal cord, it is converted to morphine and 6-monoacetyl morphine, both of which are µ-agonists with a relatively long duration of action. It is recommended for use in doses of 0.3 to 0.4 mg for cesarean delivery[189] and is widely used instead of morphine in the United Kingdom.

There are only limited data related to the use of hydromorphone for spinal analgesia. It is more commonly used epidurally, as discussed later. Limited data suggest that intrathecal hydromorphone 50 to 100 µg provides comparable analgesia with similar side effects to 100 to 200 µg of morphine, with a similar duration of action. However, it has not undergone full neurotoxicity screening and does not provide any advantage compared with morphine.[190]

Meperidine is an opioid of intermediate lipid solubility, but it also has some local anesthetic properties and has been used as the sole intrathecal agent (doses ranging from 0.5 to 1.8 mg/kg) in both obstetric and general surgery.[191,192] Smaller doses are used in combination with local anesthetics. Both 10 mg and 20 mg improve analgesia compared with placebo after cesarean delivery,[193] although side effects were more frequent with the larger dose. However, this drug is used infrequently because of the availability of other opioids and its unknown neurotoxicity profile.

Lipophilic Opioids. Fentanyl and sufentanil are used frequently in obstetrics for labor analgesia and cesarean delivery as discussed elsewhere (also Chapter XX). Sufentanil 2 to 10 µg and fentanyl 25 µg provide comparable analgesia in early labor.[194-197] In transurethral prostatectomy surgery, when combined with low-dose bupivacaine, sufentanil 5 µg provides superior analgesia compared with fentanyl 25 µg.[198] Fentanyl in doses of 10 to 30 µg is commonly used in ambulatory surgery because of its rapid onset time of 10 to 20 minutes and relatively short duration of 4 to 6 hours. Although the local anesthetic dose can be reduced and analgesia prolonged,[199] the addition of fentanyl to bupivacaine may increase side effects and delay discharge.[171]

Vasoconstrictors. Vasoconstrictors, such as epinephrine and phenylephrine, prolong the duration of sensory and motor blockade when added to local anesthetics. The mechanism of action is reduced systemic local anesthetic uptake caused by an α_1-mediated vasoconstriction. Epinephrine may also enhance analgesia via a direct α_2-mediated effect. Traditionally, epinephrine 0.1 to 0.6 mg was thought to prolong tetracaine spinal anesthesia, but not bupivacaine or lidocaine spinal anesthesia.[22] This theory was postulated because of differences in the vasodilatory action of the local anesthetic drugs; plain lidocaine and bupivacaine cause vasodilation, whereas plain tetracaine does not. However, lidocaine spinal anesthesia can be prolonged by epinephrine when measured by both two-dermatome regression in the lower thoracic dermatomes and by occurrence of pain at the operative site for procedures carried out at the level of the lumbosacral dermatomes.[200,201] Similarly, bupivacaine spinal duration may be increased, but because of the already long duration, epinephrine is not generally added to bupivacaine. There is a concern that potent vasoconstrictive action places the blood supply of the spinal cord at risk. However, there are no human data supporting this theory, and in animal studies,[164,202-204] administering either subarachnoid epinephrine (0.2 mg) or phenylephrine (5 mg) does not decrease spinal cord blood flow. Phenylephrine 2 to 5 mg prolongs both lidocaine and tetracaine spinal anesthesia to a similar extent as epinephrine.[201,205] Bupivacaine spinal anesthesia is not prolonged by phenylephrine.[206,207] Concepcion and co-workers[208] compared epinephrine (0.2 and 0.3 mg) and phenylephrine (1 and 2 mg) added to tetracaine and did not find any differences in duration between the two vasoconstrictors. Caldwell and associates[163] used larger doses of vasoconstrictors, epinephrine at 0.5 mg and phenylephrine at 5 mg, and showed that phenylephrine prolonged tetracaine spinal anesthesia significantly more than did epinephrine. The addition of phenylephrine has declined in popularity because of its association with TNS.[165,209]

α_2-Agonists. Clonidine, dexmedetomidine, and epinephrine all act on prejunctional and postjunctional α_2 receptors in the dorsal horn of the spinal cord. Activation of presynaptic receptors reduces neurotransmitter release, whereas postjunctional receptor activation results in hyperpolarization and reduction of pulse transmission.[210] In doses of 15 to 225 µg, clonidine prolongs the duration of sensory and motor blockade by approximately 1 hour and improves analgesia, reducing morphine consumption by up to 40%.[211-215] It appears to cause less urinary retention than morphine but, as with intravenous clonidine administration, spinal clonidine can also cause hypotension. A systematic review concluded that the hypotension associated with spinal clonidine was not dose-related and that the risk of bradycardia with clonidine was not increased.[216] Sedation can also occur with spinal clonidine, peaking within 1 to 2 hours and lasting up to 8 hours.[210] Dexmedetomidine is approximately 10-fold more α_2-selective than clonidine is.[217] As little as 3 μg of dexmedetomidine can prolong motor and sensory block without hemodynamic compromise.[218,219]

Other Drugs. Neostigmine in doses of 10 to 50 μg has analgesic effects after intrathecal administration.[220,221] Intrathecal neostigmine has been shown to prolong motor and sensory blockade and reduce postoperative analgesic requirements. Neostigmine inhibits the breakdown of acetylcholine, therefore increasing acetylcholine concentration, which itself is antinociceptive. It also appears to stimulate the release of nitric oxide in the spinal cord. Its benefits, however, are limited by nausea, vomiting, bradycardia, and, in higher doses, lower extremity weakness,[222,223] and is therefore not in widespread use.[224] Midazolam is a γ-aminobutyric acid receptor agonist that in doses of 1 to 2 mg appears to increase sensory and motor block and decrease analgesic requirements postoperatively, without the adverse effects observed with α_2 agonists or opioids. Early work raised concerns of spinal cord toxicity, but more recent studies suggest that it is safe.[225] Ketamine, adenosine, tramadol, magnesium, and nonsteroidal antiinflammatory drugs have also all been administered intrathecally, but further work is required to establish safety and whether these drugs have any clinical value.

Technique

Technique should be classified into a series of steps (i.e., the four Ps): preparation, position, projection, and puncture.

Preparation. Informed consent must be obtained, with adequate documentation of the discussion of risk (see Complications, discussed later). Resuscitation equipment must always be readily available whenever a spinal anesthetic procedure is performed. The patient should have adequate intravenous access and be monitored with pulse oximetry, noninvasive arterial blood pressure, and electrocardiogram. Preprepared packs are now commonly used and often contain fenestrated drapes, swabs and towels, syringes, needles, filters, spinal needles, sterilizing solution, and local anesthetic for skin infiltration. When the local anesthetic for subarachnoid injection is chosen, the duration of block should be matched with both the surgical procedure and patient variables (see Table 45.4).

The most important characteristics of a spinal needle are the shape of the tip and the needle diameter. Needle tip shapes fall into two main categories: those that cut the dura and those with a conical, pencil-point tip. The former include the Pitkin and the Quincke-Babcock needle, and the Whitacre and Sprotte needles belong to the latter group (Fig. 45.4). The orifice of the Whitacre needle is smaller. If a continuous spinal technique is chosen, use of a Tuohy or other thin-walled needle can facilitate passage of the catheter. The use of small needles reduces the incidence of post–dural puncture headache from 40% with a 22-G needle to less than 2% with a 29-G needle. The use of larger needles, however, improves the tactile sense of needle placement, and so although 29-G needles result in a very low rate of post–dural puncture headache, the failure rate is increased.[226,227] Pencil-point needles provide better tactile sensation of the different layers encountered during needle insertion but, more importantly, they reduce the incidence of post–dural puncture headache. Pencil-point needles of 25, 26, and 27-G probably represent the optimal needle choice. An introducer needle can assist with guidance of smaller-gauge spinal needles in particular. Special Luer-Lok needles and syringes for spinal kits are now also available. These have been designed to prevent inadvertent intrathecal injection but still rely on the correct drug being drawn up into the "special" connector syringe (see Fig. 45.4).

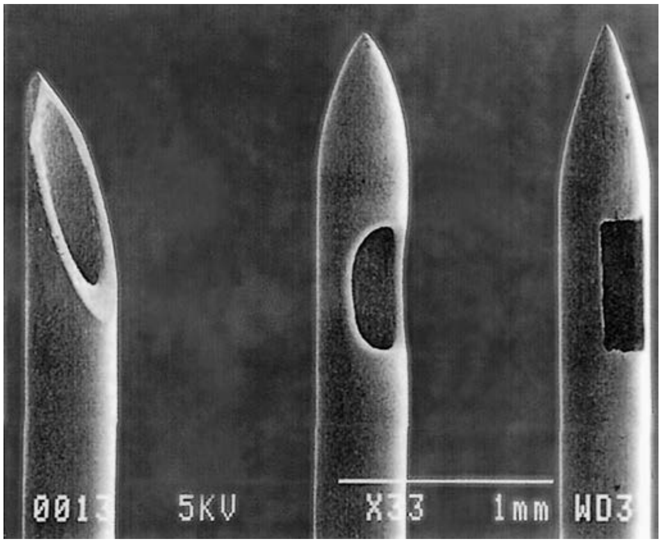

Fig. 45.4 Scanning electron micrographs of spinal needle tip designs: Quincke *(left)*, Sprotte *(middle)*, and Whitacre *(right)*. (Modified from Puolakka R, Andersson LC, Rosenberg PH. Microscopic analysis of three different spinal needle tips after experimental subarachnoid puncture. *Reg Anesth Pain Med*. 2000;25:163–169.)

Sterility is an issue of utmost importance. One of the most common organisms responsible for postspinal bacterial meningitis is *Streptococcus viridans*, which is an oral commensal, emphasizing the purpose of wearing a mask as part of a full aseptic technique. Hands and forearms must be washed and all jewelry removed. A variety of solutions may be used to clean the patient's back prior to skin puncture, such as chlorhexidine or alcohol (alone or in combination), or iodine solutions. Chlorhexidine and alcohol together have been concluded to be most effective.[229-231] It is important that chlorhexidine is allowed to dry completely before skin puncture because chlorhexidine is neurotoxic.

The recently published Practice Advisory for the Prevention, Diagnosis, and Management of Infectious Complications Associated with Neuraxial Techniques by the American Society of Anesthesiologists (ASA) Task Force on Infectious Complications Associated with Neuraxial Techniques and the ASRA[229] recommends that to prevent infection, it is important to identify patients at increased risk of infection (e.g., known bacteremia, immunocompromised) and consider alternatives, consider pre-procedure antibiotics in patients with bacteremia, ensure full asepsis including masks and use antiseptic solution such as chlorhexidine, sterile occlusive dressings, and bacterial filters. Disconnection and reconnection of neuraxial catheters should be minimized and catheters should not remain in situ longer than clinically necessary. Patients should be evaluated daily for signs of infection and if suspected then this should be promptly investigated and treated appropriately.

Position (also see Chapter 34). The three primary patient positions include the lateral decubitus, sitting, and prone positions, each of which has advantages in specific situations. The superiority of any one particular position is unclear. In the obstetric population, there have been small studies demonstrating that block operator performance was faster in the sitting position, albeit this benefit was offset by a slower onset time compared with the lateral decubitus position (see Chapter 62).[232] Current consensus guidelines state that neuraxial blocks should not be routinely performed with the patient anesthetized or deeply sedated,[76] except in those circumstances where the physician and patient conclude that benefit outweighs the risk. General anesthesia or heavy sedation can prevent a patient from recognizing warning signs of pain or paresthesia if the needle is in close proximity to nervous tissue.

A patient in the lateral decubitus position facilitates the administration of sedative medication if required, is less dependent on a well-trained assistant than for a patient in the sitting position, and is arguably more comfortable. Patients are placed with their back parallel to the edge of the operating table nearest the anesthesiologist, thighs flexed onto the abdomen, with the neck flexed to allow the forehead to be as close as possible to the knees in an attempt to “open up” the vertebral spaces. The assistant may still be invaluable during this positioning by encouraging and assisting the patient in assuming the ideal lateral decubitus position. Because of the differing proportional sizes of hips and shoulders, the spine may slope down toward the head in females, with the opposite occurring in males. The patient should be positioned so that spread of hypobaric, isobaric, or hyperbaric solution to the operative site is optimized.

Identification of the midline may be easier when the patient is placed in the sitting position, especially when obesity or scoliosis renders midline anatomy difficult to examine. Ultrasound may also be used to identify the midline (see later discussion). When placing patients in this position, a stool can be provided as a footrest and a pillow placed in the lap, or a specially designed stand may be used. The assistant helps to maintain the patient in a vertical plane while flexing the patient’s neck and arms over the pillow, relaxing the shoulders, and asking the patient to “push out” the lower back to open up the lumbar vertebral spaces. Care must be taken not to oversedate a patient in this position. Hypotension may also be more common for a person in the sitting position.

The prone position is rarely used but may be chosen when the patient is to be maintained in that position (often with the jack-knife modification) during the surgical procedure. Such cases may include rectal, perineal, or lumbar procedures. The anesthesiologist may have to aspirate for CSF because CSF pressure is minimized when insertion of the lumbar needle is carried out in this position.

Projection and Puncture. The midline approach relies on the ability of patients and assistants to minimize lumbar lordosis and allow access to the subarachnoid space between adjacent spinous processes, usually at the L2-L3, L3-L4, or the L4-L5 space. The spinal cord ends at the level of L1-L2 and so needle insertion above this level should be avoided. The intercristal line is the line drawn between the two iliac crests and traditionally corresponds to the level of the L4 vertebral body or the L4-L5 interspace, but the reliability of this landmark is questionable as demonstrated by recent ultrasonography studies.[233] Once the appropriate space has been selected, a subcutaneous skin wheal of local anesthetic is developed over this space, and the introducer is inserted at a slight cephalad angle of 10 to 15 degrees through skin, subcutaneous tissue, and supraspinous ligament to reach the substance of the interspinous ligament. The introducer is grasped with the palpating fingers and steadied while the other hand is used to hold the spinal needle like a dart, and the fifth finger is used as a tripod against the patient’s back to prevent patient movement and unintentional insertion to a level deeper than intended. The needle, with its bevel parallel to the midline, is advanced slowly to heighten the sense of tissue planes traversed and to prevent skewing of nerve roots, until the characteristic change in resistance is noted as the needle passes through the ligamentum flavum and dura. On passing through the dura, there is often a slight “click” or “pop” sensation. The stylet is then removed, and CSF should appear at the needle hub. The smaller the needle diameter, the longer the wait for CSF flow, particularly if the patient is not in the sitting position. If the CSF does not flow, the needle might be obstructed and rotation in 90-degree increments can be undertaken until CSF appears. If CSF does not appear in any quadrant, the needle should be advanced a few millimeters and rechecked in all four quadrants. If CSF still has not appeared and the needle is at a depth appropriate for the patient, the needle and introducer should be withdrawn and the insertion steps should be repeated. A common reason for failure is insertion of the needle off the midline (Fig. 45.5).

After CSF is freely obtained, the dorsum of the anesthesiologist’s nondominant hand steadies the spinal needle against the patient’s back while the syringe containing the therapeutic dose is attached to the needle. CSF is again freely aspirated into the syringe, and the anesthetic dose is injected at a rate of approximately 0.2 mL/s. After completion of the injection, 0.2 mL of CSF can be aspirated into the syringe and reinjected into the subarachnoid space to reconfirm location and clear the needle of the remaining local anesthetic.

The paramedian approach exploits the larger “subarachnoid target” that exists if a needle is inserted slightly lateral to the midline (Fig. 45.6). The paramedian approach may be especially useful in the setting of diffuse calcification of the interspinous ligament. The most common error when using the paramedian technique is that the needle entry site is placed too far off midline, which makes the vertebral laminae barriers to insertion of the needle. In the paramedian approach, a skin wheal is raised 1 cm lateral and 1 cm caudad to the corresponding spinous process. A longer needle (e.g., 3-5 cm) is then used to infiltrate deeper tissues in a cephalomedial plane. The spinal introducer and needle are next inserted 10 to 15 degrees off the sagittal plane in a cephalomedial plane (see Fig. 45.6). Similar to the midline approach, the most common error is to angle the needle too far cephalad on initial insertion. Nevertheless, if the needle contacts bone, it is redirected slightly in a cephalad direction. If bone is again contacted, but at a deeper level, the slight cephalad angulation is continued because it is likely that the needle is being “walked up” the lamina. As

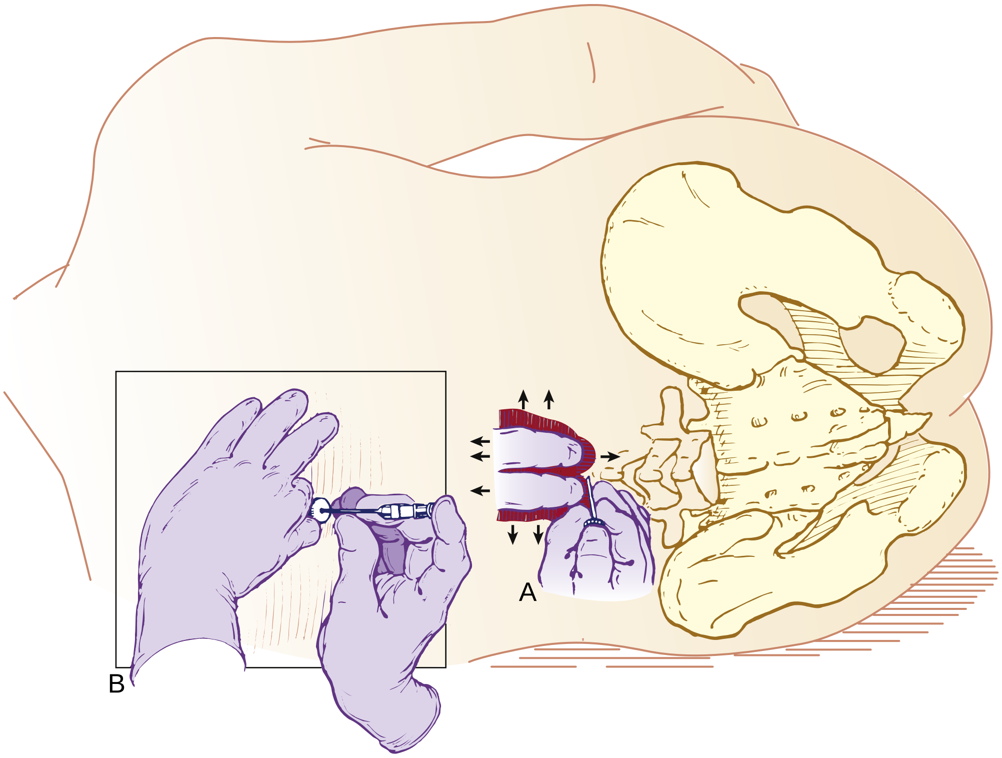

Fig. 45.5 Insertion of the spinal needle. (A) The palpating fingers are "rolled" in a side-to-side and a cephalad-to-caudad direction to identify the interspinous space. (B) During needle insertion, the needle should be stabilized in a tripod fashion while placed in the hand, similar to a dart being thrown.

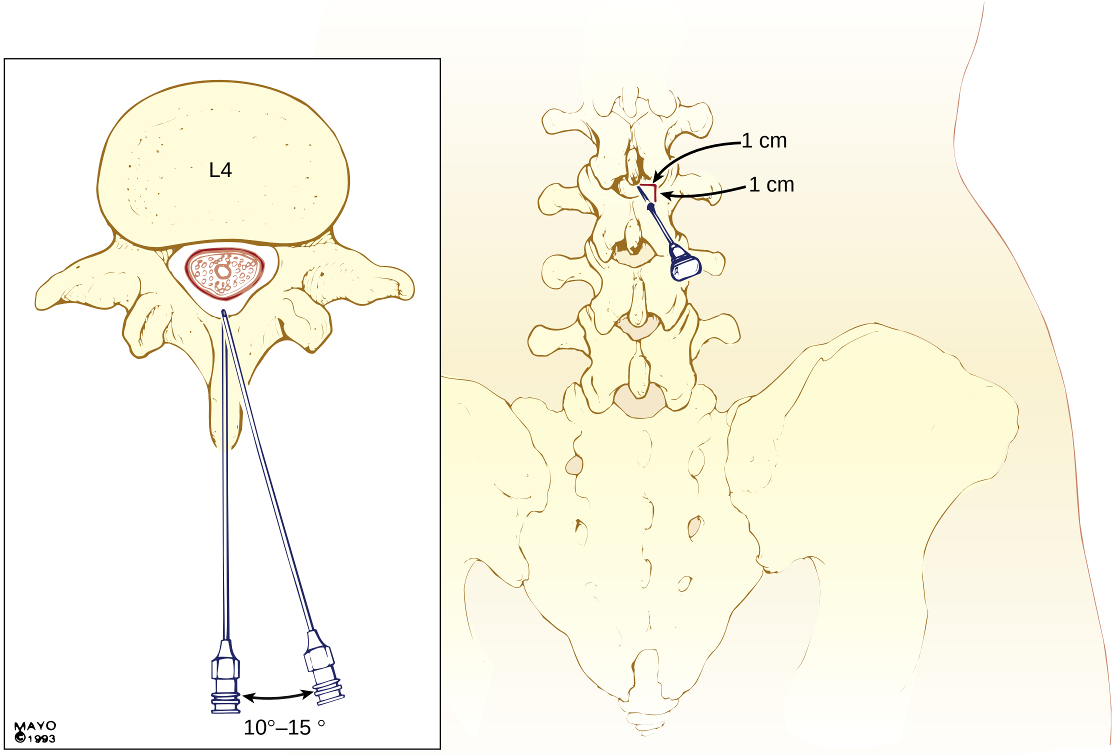

Fig. 45.6 Vertebral anatomy of the midline and paramedian approaches to centroneuraxis blocks. The midline approach highlighted in the inset requires anatomic projection in only two planes: sagittal and horizontal. The paramedian approach shown in the inset and in the posterior view requires an additional oblique plane to be considered, although the technique may be easier in patients who are unable to cooperate in minimizing their lumbar lordosis. The paramedian needle is inserted 1 cm lateral and 1 cm caudad to the caudad edge of the more superior vertebral spinous process. The paramedian needle is inserted approximately 15 degrees off the sagittal plane, as shown in the inset. (Courtesy the Mayo Foundation, Rochester, MN.)

in the midline approach, the characteristic feel of the ligaments and dura is possible, but only once the ligamentum flavum is reached because the needle this time is not passing through the supraspinous and interspinous ligaments. After CSF is obtained, the block is carried out in a manner similar to that described for the midline approach.

SPECIAL SPINAL TECHNIQUES

Continuous Spinal Anesthesia

Continuous spinal anesthesia allows incremental dosing of local anesthetic and therefore predictable titration of the block to an appropriate level, with better hemodynamic stability than a single-shot spinal.[40] It is useful in controlling arterial blood pressure in such patients with severe aortic stenosis or pregnant women with complex cardiac disease. In obstetrics, it may also be used in patients with morbid obesity and where previous spinal surgery may hinder epidural spread. Spinal catheters also serve as an alternative to the CSE technique for prolonged cases and have been used in selected patients for laparotomies where general anesthesia may be too great a risk.[234] If a continuous spinal anesthetic is undertaken, a needle with a laterally facing opening may be used to perform the lumbar puncture (Fig. 45.7). A midline or paramedian approach may be used, with some experts suggesting that use of the paramedian approach facilitates insertion of the catheter.[235] The catheter should be threaded 2 to 3 cm into the subarachnoid space and the needle withdrawn over the catheter. The catheter must never be withdrawn back into the needle shaft in case a piece of the catheter is sheared off and left in the subarachnoid space. Care must also be taken to ensure that the catheter is not inserted more deeply into the subarachnoid space when the needle is withdrawn over the catheter. Spinal microcatheters exist, but these have been associated with cauda equina syndrome,[5] probably because of lumbosacral pooling of local anesthetic. Catheter-over-the-needle devices are also available for use with continuous spinal anesthesia, with the advantage of minimizing leakage of CSF around the catheter,[236] but these may be more difficult to insert.[236] Finally, epidural doses of local anesthetic should not be infused or “bloused” into spinal catheters, and strict attention must also be paid to sterile technique.

Unilateral Spinal Anesthesia and Selective Spinal Anesthesia

The terms *unilateral spinal anesthesia* and *selective spinal anesthesia* overlap slightly, but both refer to small-dose techniques that capitalize on baricity and patient positioning to hasten recovery. A recent systematic review found that a dose of 4 to 5 mg of hyperbaric bupivacaine with unilateral positioning was adequate for knee arthroscopy.[171] This technique has also been used for unilateral inguinal hernia repair with a dose of 8 mg bupivacaine. In selective spinal anesthesia, minimal local anesthetic doses are used with the goal of anesthetizing only the sensory fibers to a specific area.[237,238] These doses are discussed in more detail in the chapter on anesthesia for ambulatory surgery (see Chapter 72).

BLOCK MONITORING

Once the spinal anesthetic has been administered, the onset, extent, and quality of the sensory and motor blocks must be assessed while heart rate and arterial blood pressure are also being monitored for any resultant sympathetic blockade. There are many methods of assessing sensory block, but cold sensation and pinprick representing C- and A-delta fibers, respectively, are used more often than mechanical stimuli such

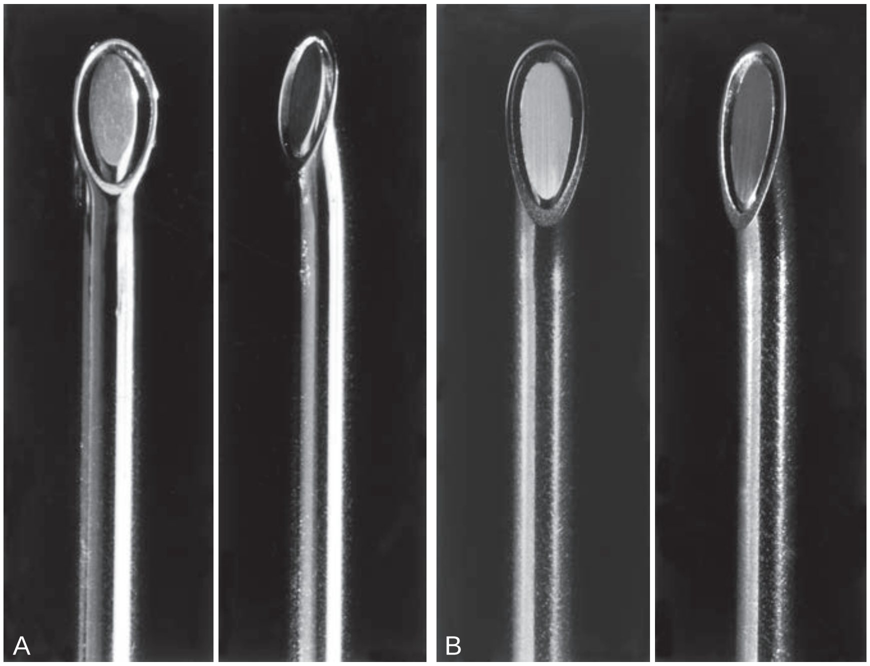

Fig. 45.7 Examples of continuous spinal needles, including a disposable, 18-G Hustead (A) and a 17-G Tuohy (B) needle. Both have distal tips designed to direct the catheters inserted through the needles along the course of the bevel opening; 20-G epidural catheters are used with these particular needle sizes.

as touch, pressure, and von Frey hairs, which reflect the A-beta nerves. Loss of sensation to cold usually occurs first, verified using an ethyl chloride spray, ice, or alcohol, followed by the loss of sensation to pinprick, verified using a needle that does not pierce the skin.[20] Finally, loss of sensation to touch occurs. Dermatomal block height also varies with the method of assessment, but in general, peak height is measured most cephalad using loss of cold, and is measured lower with pinprick, and lowest with touch.[239] Assessing dermatomal block height assumes that absence of sensation to these stimuli equates to blockade of the nociceptive fibers, but this is not necessarily the case.[240] Other electrical and experimental chemical methods of assessing pain have been used but gentle pinprick remains the simplest.[91,241] Motor block may also be measured in a variety of ways. The modified Bromage scale (Box 45.1) is most commonly used, although this represents only lumbosacral motor fibers.[242] Electromyography and pulmonary function tests have been used to measure abdominal and thoracic motor function, but these are neither practical nor specific.

In practice, the combination of sympathetic block with an adequate sensory level and motor block (inability to straight-leg raise ensures at least that lumbar nerves are blocked) is used to confirm spinal efficacy. Ensuring that the level of block using cold or pinprick is two to three segments above the expected level of surgical stimulus is commonly considered adequate.

Epidural Anesthesia

FACTORS AFFECTING EPIDURAL BLOCK HEIGHT

The epidural space is a collapsible, distensible reservoir through which drugs spread and are removed by diffusion, vascular transport, and leakage. Spread of anesthetic within the epidural space, and subsequent block height, is related to a variety of factors, not all of which can be manipulated by the anesthesiologist (Table 45.5).[26]

BOX 45.1 **Modified Bromage Scale**

- 0: No motor block
- 1: Inability to raise extended leg; able to move knees and feet
- 2: Inability to raise extended leg and move knee; able to move feet
- 3: Complete block of motor limb

Drug Factors

The volume and total mass of injectate are the most important drug-related factors that affect block height after the administration of local anesthetic in the epidural space. As a general principle, 1 to 2 mL of solution should be injected per segment to be blocked. Although additives such as bicarbonate, epinephrine, and opioids influence onset, quality, and duration of analgesia and anesthesia, these do not affect spread.

Patient Factors

Age can influence epidural block height.[26] There appears to be a stronger correlation with age and block height in thoracic epidurals, with one study suggesting that 40% less volume is required in the elderly (see Chapter 65).[243] Possible reasons include decreased leakage of local anesthetic through intervertebral foramina, decreased compliance of the epidural space in the elderly resulting in greater spread, or an increased sensitivity of the nerves in the elderly. As with spinal anesthesia, it appears that only the extremes of patient height influence local anesthetic spread in the epidural space. Weight is not well correlated with block height in the settings of either lumbar or TEA.[244] Less local anesthetic is required to produce the same epidural spread of anesthesia in pregnant patients. Although this may be in part a result of engorgement of epidural veins secondary to increased abdominal pressure, the effect also occurs in early pregnancy.[245] Also, continuous positive airway pressure increases the height of a thoracic epidural block.[246,247]

Procedure Factors

The level of injection is the most important procedure-related factor that affects epidural block height. In the upper cervical region, spread of injectate is mostly caudal, in the midthoracic region spread is equally cephalad and caudal, and in the low thoracic region spread is primarily cephalad.[248] After a lumbar epidural, spread is more cephalad than caudal. Some studies suggest that the total number of segments blocked is less in the lumbar region compared with thoracic levels for a given volume of injectate. Patient position has been shown to affect spread of lumbar epidural injections, with preferential spread and faster onset to the dependent side in the lateral decubitus position.[249] The sitting and supine positions do not affect epidural block height. However, the head-down tilt position does increase cephalad spread in obstetric patients.[250] Needle bevel direction

TABLE 45.5 Factors Affecting Epidural Local Anesthetic Distribution and Block Height

	More Important	Less Important	Not Important
Drug factors	Volume Dose	Concentration	Additives
Patient factors	Elderly age Pregnancy	Weight Height Pressure in adjacent body cavities	
Procedure factors	Level of injection	Patient position	Speed of injection Needle orifice direction

and speed of injection also do not appear to influence the spread of a bolus injection.

PHARMACOLOGY

Local anesthetics for epidural use may be classified into short-, intermediate-, and long-acting drugs. A single bolus dose of local anesthetic in the epidural space can provide surgical anesthesia ranging from 45 minutes up to 4 hours depending on the type of local anesthetic administered and the use of any additives (Table 45.6). Most commonly, an epidural catheter is left in situ so that local anesthetic–based anesthesia or regular analgesia can be extended indefinitely.

Short-Acting and Intermediate-Acting Local Anesthetics

Procaine. Similar to spinal anesthesia, procaine is not commonly used for epidural anesthesia. Five-percent procaine has a slow onset and the resultant block can be unreliable and of poor quality.

Chloroprocaine. Chloroprocaine is available preservative-free in 2% and 3% concentrations for epidural injection, with the latter preferable for surgical anesthesia because the former may not produce muscle relaxation. The 3% preparation has an onset time of 10 to 15 minutes and a duration of up to 60 minutes. Adding epinephrine prolongs the block for up to 90 minutes. Before the development of preservative-free preparations, large volumes (>25 mL) of chloroprocaine had been associated with deep, aching, burning lumbar back pain.[251] This was thought to be secondary to the ethylenediaminetetraacetic acid that chelated calcium and caused a localized hypocalcemia. In addition, chloroprocaine can antagonize the effects of epidural morphine.[242] This may be a result of opioid receptor antagonism by either the chloroprocaine or a metabolite. Antagonism of an intracellular messenger and decreased morphine availability caused by a reduction in perineural pH are also proposed mechanisms. However, morphine and chloroprocaine seem like an illogical combination because the beneficial ultrashort duration of action of chloroprocaine is offset by the addition of morphine.

Articaine. Articaine is not widely used for epidural anesthesia and has not been studied extensively. When 2% articaine was compared with epidural lidocaine in one study, it had a similar latency, spread, duration, and motor block.[252] It has also been used for obstetric epidural analgesia.[148]

Lidocaine. Lidocaine is available in 1% and 2% solutions; it has an onset time of 10 to 15 minutes and a duration of up to 120 minutes, which can be extended to 180 minutes with the addition of epinephrine. Unlike spinal anesthesia, TNS are not commonly associated with epidural lidocaine.[253]

Prilocaine. Prilocaine is available in 2% and 3% solutions. The 2% solution produces a sensory block with minimal motor block. Onset time is approximately 15 minutes, with a duration of approximately 100 minutes. When compared with lidocaine, prilocaine has a more marked sensory blockade and a longer duration (different from Cousins).[242] In large doses, prilocaine is associated with methemoglobinemia.[156,254]

Mepivacaine. Mepivacaine is available as 1%, 1.5%, and 2% preservative-free solutions. The 2% preparation has an onset time similar to lidocaine of approximately 15 minutes, but a slightly longer duration (up to 200 minutes with epinephrine), making it a preferred option by some centers for surgery of an intermediate duration.

Long-Acting Local Anesthetics

Tetracaine. Tetracaine is not widely used for epidural anesthesia because of unreliable block height and, in larger doses, systemic toxicity.

Bupivacaine. Bupivacaine is available in 0.25%, 0.5%, or 0.75% preservative-free solutions. The onset time is around 20 minutes with a duration of up to 225 minutes, which is prolonged only slightly by the addition of epinephrine (to 240 minutes). More dilute concentrations such as 0.125% to 0.25% can be used for analgesia. However, disadvantages include cardiac and central nervous system toxicity and the potential for motor block from larger doses. Solutions of 0.5% and 0.75% are used to provide surgical anesthesia.

TABLE 45.6 Comparative Onset Times and Analgesic Durations of Local Anesthetics Administered Epidurally in 20- to 30-mL Volumes

			DURATION (MIN)	
Drug	**Concentration (%)**	**Onset (min)**	**Plain**	**1:200,000 Epinephrine**
2-Chloroprocaine	3	10-15	45-60	60-90
Lidocaine	2	15	80-120	120-180
Mepivacaine	2	15	90-140	140-200
Bupivacaine	0.5-0.75	20	165-225	180-240
Etidocaine	1	15	120-200	150-225
Ropivacaine	0.75-1.0	15-20	140-180	150-200
Levobupivacaine	0.5-0.75	15-20	150-225	150-240

Modified from Cousins MJ, Bromage PR. Epidural neural blockade. In: Cousins MJ, Bridenbaugh PO, eds. *Neural Blockade in Clinical Anesthesia and Management of Pain*. Philadelphia: JB Lippincott; 1988;255.

Liposomal bupivacaine is currently under investigation for epidural use. An epidural bolus of liposomal 0.5% bupivacaine provided similar onset but longer-lasting analgesia to boluses of plain bupivacaine.[255] It does not appear to be more toxic than plain bupivacaine or to have a differing cardiac safety profile. The benefit, as with extended-release morphine (discussed later), is the lack of need for an epidural catheter. Conversely, such extended-release boluses are less titratable if for any reason the epidural needs to be terminated early.

Levobupivacaine. Levobupivacaine can be used as an epidural local anesthetic in 0.5% to 0.75% concentrations for surgical anesthesia, whereas analgesia can be achieved with concentrations of 0.125% to 0.25%. Levobupivacaine administered epidurally has the same clinical characteristics as bupivacaine.[129,256,257] The advantage of levobupivacaine is that it is less cardiotoxic compared with bupivacaine.[175,258]

Ropivacaine. Ropivacaine is available in 0.2%, 0.5%, 0.75%, and 1.0% preservative-free preparations. For surgical anesthesia, 0.5% to 1.0% is used, whereas 0.1% to 0.2% is used for analgesia. Ropivacaine is associated with a superior safety profile compared with bupivacaine.[259,260] Data from animal models suggest that bupivacaine has a 1.5 to 2.5 lower seizure threshold than ropivacaine. Ropivacaine is also less cardiotoxic. When compared with bupivacaine and levobupivacaine, ropivacaine at equivalent concentrations has a relatively similar clinical profile. Ropivacaine has a slightly shorter duration of action and less motor block, although the reduced motor block may in fact reflect different potencies of the drugs rather than a true motor-sparing effect of ropivacaine. Epidurally administered ropivacaine is 40% less potent than bupivacaine.[179,180,261]

Epidural Additives

Vasoconstrictors. Epinephrine reduces vascular absorption of local anesthetics in the epidural space. The local anesthetics vary in their responsiveness to epinephrine. The effect is the most with lidocaine,[262] mepivacaine, and chloroprocaine (up to 50% prolongation), with a lesser effect with bupivacaine, levobupivacaine, and etidocaine, and a limited effect with ropivacaine, which already has intrinsic vasoconstrictive properties (see Table 45.6). Epinephrine itself may also have some analgesic benefits because it is absorbed into the CSF, where it can act on dorsal horn α_2 receptors.[263] Phenylephrine has been used in epidural anesthesia less widely than in spinal anesthesia, perhaps because it does not reduce peak blood levels of local anesthetic as effectively as epinephrine does during epidural use.[264]

Opioids. Opioids synergistically enhance the analgesic effects of epidural local anesthetics, without prolonging motor block. A combination of local anesthetic and opioid reduces the dose-related adverse effects of each drug independently. The analgesic benefits of neuraxial opioids must be balanced against the dose-dependent side effects. As with intrathecal opioids, there appears to be a therapeutic ceiling effect above which only side effects increase. Opioids may also be used alone, particularly when there are concerns regarding hemodynamic instability. Epidural opioids work by crossing the dura and arachnoid membrane to reach the CSF and spinal cord dorsal horn. Lipophilic opioids, such as fentanyl and sufentanil, partition into epidural fat and therefore are found in lower concentrations in CSF than hydrophilic opioids, such as morphine and hydromorphone. Fentanyl and sufentanil are also readily absorbed into the systemic circulation, and several studies suggest that this is the principal analgesic mechanism.[265,266]

Epidural morphine is administered as a bolus of 1 to 5 mg, with an onset time of 30 to 60 minutes and duration of up to 24 hours. The optimal dose that balances analgesia while minimizing side effects is 2.5 to 3.75 mg.[267] Alternatively, morphine can be administered continuously in doses of 0.1 to 0.4 mg/h through an epidural catheter. Hydromorphone is more hydrophilic than fentanyl but more lipophilic than morphine. It can be administered as a bolus of 0.4 to 1.5 mg, with onset at 15 to 30 minutes and a duration of 18 hours. Hydromorphone used as an infusion is delivered at rates between 5 and 20 μg/h. The onset of epidural fentanyl and sufentanil is 5 to 15 minutes and lasts only 2 to 3 hours. Bolus doses of 10 to 100 μg may be used to provide analgesia. Diamorphine is available in the United Kingdom and used in doses of 2 to 3 mg as epidural boluses, or approximately 0.05 mg/mL in an infusion.

DepoDur is an extended-release liposomal formulation of morphine used as a single-shot lumbar epidural dose, thereby avoiding issues and side effects of a continuous local anesthetic infusion and indwelling catheters, particularly in patients receiving anticoagulants. When administered before surgery (or after clamping of the cord in cesarean deliveries), DepoDur can provide up to 48 hours of pain relief.[268,269] A dose of 10 to 15 mg is recommended for lower abdominal surgery, and 15 mg is recommended for major lower limb orthopedic surgery.
